CCD detector to achieve discrimination in the other spatial direction. In certain circumstances it may be advantageous to be able to adjust the pinhole size to achieve higher S/N at the expense of confocal spatial resolution and this is only possible in some of the commercial systems.

Coupling the light between the laser and the microscope for excitation and the microscope and the spectrometer for scattered light can be achieved either by direct optical coupling or by the use of fiber optics. The former is clearly more efficient, whilst the latter provides greater flexibility, in being able to remove the Raman head from the microscope to make adjustments without requiring the system to be realigned.

As with the conventional research optical microscopes, there has been a shift towards infinity corrected optics. There is little advantage in the Raman experiment to using anything but the simplest objectives, as essentially monochromatic light is being brought to a focus on-axis and there is no need to be concerned with wide-field or chromatic image aberrations. In fact, some of the higher quality objectives are less efficient because their light transmission characteristics are lower. With NIR excitation at 780 nm it is advantageous to use NIR objectives optimized for high light throughput in the NIR. However, such objectives may be prohibitively expensive and hence only recommended for extremely low S/N applications.

3.3.3 Rayleigh Filters
The most influential component in the recent revolution in Raman instrumentation has to be the holographic notch filter for Rayleigh rejection. It is this small but extremely efficient narrow band rejection filter that is now at the heart of almost all commercial instruments. In the context of Raman microscopy, the use of this filter as a beamsplitter has led to very efficient designs for laser injection and scattered light collection from microscopes.

3.3.4 Monochromators
All commercial systems designed specifically for Raman microscopy are configured around single-pass imaging monochromator systems. There are options based around astigmatism-corrected classical Czerny–Turner designs, stigmatic on-axis spectrographs and the more recent transmission hologram grating designs. All designs are optimized for CCD detection and maintenance of the slit image on to the detector.

3.3.5 Detectors
Again, with no real exceptions, microscope systems are equipped with CCD detectors. There are several options. Back-thinned CCD chips are now manufactured reliably enough to not suffer from gross variations in pixel–pixel quantum efficiency and small variations are easily handled by correct instrument calibration (see section 3.2.2). These chips represent the most effective detectors, particularly the deep-depletion chips which have an enhanced IR region response, giving better efficiency with 780-nm excitation. Conventional front illuminated CCDs are cheaper and work perfectly well with visible excitation, most effectively at 633 nm (HeNe).

CCD camera cooling options are between multistage Peltier (both air and water) and liquid nitrogen. For the vast majority of practical applications, air-cooled CCDs are adequate (most Raman experiments now being shot noise limited). For the most demanding of applications with long integration times of an hour or more, liquid nitrogen cooling may be appropriate.

3.4 Instrumentation for Raman Imaging

The previous section described the instrumentation appropriate for point microspectroscopic investigations. This section describes the additional complexity required to produce Raman images.

3.4.1 Point Mapping
The adaptation of a point microspectroscopic system to point mapping is made simply by the addition of a software-controlled motorized stage. The software clearly must be interfaced with the spectrometer acquisition software but in most cases this has been dealt with in the current commercial designs.

3.4.2 Line Mapping Instrumentation
The line mapping approach requires two criteria to be met. First, the laser illumination has to be projected across a line on the sample and, second, the scattered light from that line has to be imaged on to the entrance slit of the spectrometer, preserving the spatial resolution along the line.

In the line scanning experiment it is clear that it is best to arrange for the illumination intensity across the line to be uniform in order to confidently interpret the spectral intensity variations.

There are three main methods of illuminating the line on the sample. These are the use of galvanometer-driven spinning mirrors, cylindrical lenses, or the more recent Powell lens optic. Even if illumination on to the sample is arranged to be uniform, there will be a transfer function for the line through the microscope and spectrometer optic train that may result in a nonuniform instrument response function. With care this could be calibrated out of the system but is an added
complexity. The direct coupling of the line illumination to the slit of the monochromator implies that confocality (particularly the depth resolution in the z-direction) is lost in the line scanning experiment in the cases using lens optics.

Obtaining a line scanning profile using the spinning mirrors method has the advantage of preserving the confocality in the z-direction but still produces a variation in the illumination intensity along the line. The main advantage of using a cylindrical lens is that the system is easier to align but, along with the loss of confocality, there remain intensity variations in the line at the extremities. However, the use of a Powell lens for line imaging has reduced these illumination intensity variations along the line to less than 10\%.\(^{30,31}\)

### 3.4.3 Comparison of Line Mapping with Point Mapping

The claim for line mapping is that the method can lead to decreased acquisition times for the same S/N. In a qualitative imaging sense, this is certainly correct. However, point mapping benefits from a simpler on-axis optical design and as a consequence the instrument response at each pixel in the spectral image data set is reliably quantitative. There is no guarantee that this is the case along the line in a line scanning approach. For a quantitative analysis, instrument response corrections have to be made for uneven illumination and uneven light throughput efficiency along the line. The second clear disadvantage with lens-based systems is the loss of confocality, which decreases the depth discrimination in the image. Confocality often proves to be important in real samples.

The major advantage will be achieved when there is excess laser power available that cannot be focused down on to a single point on the sample without power damage. Then the ability to put an appropriate power density simultaneously along a line and collect the spectral information in parallel is clearly desirable.

This method also allows simultaneous collection of data along a one-dimensional spatially resolved axis and brings timescales down to the second/minute range for collection of quality spectral information, acquired across a boundary for example. This may provide interesting opportunities for kinetic studies of interfacial transport phenomena.

The line focusing method can be used to smear out sample heterogeneity and provide a simple bulk spectrum from a region of heterogeneous material. The spectral information collected across the line can be averaged by simply binning the information on the complete vertical (spatial) axis of the CCD chip. This approach results in an improvement in the S/N over point microscopy along the line and subsequent averaging. In all cases there is a decrease in the motorized stage movement (dead) time during image as the stage only has one direction in which to move.

The disadvantages of the line mapping approaches have been indicated above. Essentially, the loss of confocality in the lens-based approaches can be a serious limitation in complex systems. The spinning mirror approach can conserve the confocality but results in added complexity in both the instrumentation and the line-up process. All of the approaches suffer from some degree of line response function (from both uneven illumination and photometric variation in the line transfer function through the optics to the spectrometer).

In summary, there have been only limited attempts to commercialize a line imaging system, based on either spinning mirrors or cylindrical optics. These instruments have met with very limited success. No commercial devices have yet appeared using Powell lenses, which provide the best option for uniform line illumination.\(^{30,31}\) It appears that the advantages for line mapping over the simpler point mapping approach have not been valuable enough to make such attempts commercially successful.

### 3.4.4 Raman Microscopy Instrumentation

In the case of Raman microscopy, there are again two critical criteria. First, a wide field of view has to be illuminated by the laser and, second, the scattered light from that field of view has to be imaged through a spectral section filter on to a camera at the image plane.

In most cases, the illumination of a wide field of view has been achieved by defocusing the laser. This will inevitably result in some uneven illumination. An alternative approach to illumination methods is the use of two nonresonant spinning mirrors\(^{33}\) and this is claimed to achieve far more even illumination (but at the cost of added instrument complexity).

There are several approaches to the spectral image filtering. The simplest approach is to use an imaging monochromator, with the slit opened to allow the image to pass through the system on to the CCD.\(^{34,35}\) The images obtained are at very low spectral resolution and so the practical application of this approach is limited. Better resolution, of the order of 25 cm\(^{-1}\), is obtained by using dielectric filters as the spectral selection method. A set of filters can be employed which take advantage of the change in transmission maximum of these filters on tilting to cover a wide spectral range with a limited filter set.\(^{24,25,36}\) A commercial device based upon this technology is available. An obvious alternative is to use a fixed filter and tune the excitation wavelength\(^{37}\) but this increases the complexity of the laser used.
Electronically tunable image filters include acousto-optic tuneable filters (AOTFs).\textsuperscript{38–40} The AOTF essentially creates an anisotropic spectral image filter which causes image blurring at high magnification.\textsuperscript{41} This blurring can be eliminated to some degree by image processing. However the AOTF is limited by its minimum 30 cm\textsuperscript{−1} resolution and there have been no attempts to produce a commercial device based upon AOTF technology.

More recent developments include Fabry–Perot approaches\textsuperscript{42} and liquid-crystal tuneable filters (LCTFs).\textsuperscript{43–45} LCTFs have proved more practical, being rapidly electronically tuneable, with a large acceptance angle, and being shown to be free of image distortion effects. They also provide 8 cm\textsuperscript{−1} resolution at typical distortion wave-lengths and so rival the spectral resolution achievable with conventional spectrometers. Two commercial devices are currently available using LCTF technology.

### 3.4.5 Comparison of Raman Microscopy with other Imaging Methods

The Raman microscopy approach, like the line illumination methods, has the advantage in cases where the full laser power cannot be focused down to a small spot on the sample due to laser damage. In practice, because of the decreased laser power per pixel with this approach, it is more common to use spectral microscopy to collect a single wavenumber image or at most a few key selected wavenumber images. In these circumstances, the selected spectral images may be collected relatively quickly. Therefore for inspection of a large number of similar samples for heterogeneity, where there is very clear spectral contrast which can be determined with only a few selected wavelengths, the spectral microscopy approach is ideal.

However, the Raman microscopy approach has its drawbacks which are detailed below:

- **Spectral resolution.** Inherent in the global microscopy approach is the use of filters. Such filtering methods are often limited in their spectral resolution as indicated above and this could be restrictive in many applications. However, the best filters are LCTFs and these are now available with 8 cm\textsuperscript{−1} resolution\textsuperscript{43,45} and so rival the spectral resolution that is commonly used with point and line mapping instruments. However, it should be noted that the theoretical light throughput efficiency of LCTFs is 50% maximum (being a polarization-based device) and practically this falls to the region of 20% or worse at most wavelengths.

- **Uneven illumination.** The most common method of global illumination is to defocus the laser on to the sample. The typical Gaussian beam profile and the delivery optics will result in uneven illumination across the image. The distribution profile could be corrected by ratioing the instrument response using the signal from a standard (flat) sample. A patent has recently been applied for which promises to deliver far more uniform illumination across the field of view.\textsuperscript{33}

  - **Depth of field in the image.** Clearly the spectral microscopy approach does not provide confocal depth discrimination in the spectral image. Deconvolution methods can be used to improve the spatial resolution in the z-direction\textsuperscript{46} but have yet to be routinely applied even in the commercial instruments. Therefore this approach is currently best suited to surface inspection or situations where the depth information is not important.

  - **Lack of “post-interpretation”**. Images are collected at prechosen wavelengths, rather than full spectral information per point being collected. An intimate knowledge of the spectroscopy of the system (coupled with an assumption that nothing unexpected occurs) is therefore a necessary prerequisite to investigations using spectral microscopy. If subsequent spectral information is required, the sample has to be re-presented to the instrument and point microspectroscopy performed.

- **Quantitative accuracy.** In addition to the problems associated with uneven illumination and transfer function of the image to the camera, all of these spectral filtering methods simply collect all the light present at the chosen wavenumber shift including any background fluorescence. One approach to eliminate this is to take an image at a wavenumber shift “close” to the Raman band of interest but where no Raman scattering is expected. Subtraction of this “background” image or division of the Raman image by the background image (so-called flat-fielding) will then result in a more accurate image relating to the Raman intensity. Owing to the complex nature of backgrounds the quantitative accuracy of such approaches has to be questioned.

The main advantage of the Raman microscopy approach is the speed at which a single Raman image of the intensity contrast at a particular wavenumber can be obtained. Images are often presented at far higher image fidelity (pixel density) than are obtained with the mapping approaches (although the pixel density does not, of course, necessarily equate with spatial resolution, which is more directly related to the excitation wavelength, the numerical aperture of the objective lens and the optical properties of the sample itself).
Therefore the Raman microscopy approach is ideal for two-dimensional imaging with samples of high spectral contrast (where a few key wavenumber images can completely define the sample) and where depth resolution is not an issue. It also lends itself to the study of kinetic processes where spatial heterogeneity is important and to possible three-dimensional investigations which are described in the next section.

3.5 Three-dimensional Imaging Using Raman Spectroscopy

The confocal Raman microscope has the ability, in principle, to perform a depth-profiling function in much the same way as an optical confocal system (with the same limitations associated with scattering samples and laser absorption). Therefore, in principle, the ability to generate three-dimensional spectrally resolved images is available, using the \( z \)-axis control of the microscope stage.

Mapping and image reconstruction techniques are going to take several hours to complete, even with the most efficient hardware, but in static systems this may have some practical value. In this case image distortion is observed in the \( z \)-axis due to the point spread function of the observed Raman intensity and hence image deconvolution techniques may have to be used on the spectral image data slices to create a more faithful image in three dimensions.

Image deconvolution has also been applied to vertical sets of two-dimensional, wide-field, Raman microscopy images to produce a three-dimensional representation.\(^{46}\)

In any real practical application of three-dimensional Raman imaging, the Raman microscopy approach at a limited set of wavelengths is likely to prove more successful\(^{47}\) although a direct comparison between the two approaches of Raman microscopy–deconvolution and three-dimensional confocal Raman point mapping has yet to be made.

4 EXPERIMENTAL CONSIDERATIONS

There are several other experimental issues that should be considered with regard to Raman microscopy and these are reviewed here.

4.1 Detection Limits

The detection limits of a range of surface-specific techniques are listed by Aller.\(^{48}\) For Raman microscopy, the relative limit is listed as 100 ppm but the absolute limit is \(10^{-12}\) g due to the spatial resolution at 1 \(\mu\)m which can be achieved using confocal optics. These detection limits assume that you can concentrate on a particular spot in a system where the analyte in question is known to reside. Spectral quality is then obtained by lengthy data acquisition as appropriate to achieve the 100-ppm discrimination.

A far more practical rule of thumb is that, for most organic species, levels of 1% should be observable by Raman. Specific molecules can vary however by a couple of orders of magnitude with respect to this estimate and specific detection also depends upon background and the presence or absence of other spectrally similar species.

4.2 Sampling Conditions

One of the major advantages of Raman microspectroscopy is that it is essentially a noninvasive, in situ tool, which performs under ambient conditions. The backscatter arrangement of the Raman microscope means that the technique is independent of the surface or substrate on which study is taking place.

The most important consequence of the ability to study systems under ambient conditions with little sample preparation is that Raman investigations will be easily geared up to “look see” investigations of chemical heterogeneity.

The poor scattering efficiency of water means that aqueous systems are studied without interference. This contrasts with the mid-IR where large regions of the spectrum are obscured by the IR absorbance spectrum of water.

4.3 Quantitative Applications

Raman spectra are capable of quantitative interpretation. If an internal standard is available, then such use can be extremely confident. However, without an internal standard, photometric accuracy, particularly in microscope systems, has to be considered carefully, as does the effect of polarization when dealing with anisotropic systems.

Nevertheless, relative quantitation between species in Raman microspectroscopy is more easily obtained, especially if a system calibration method is employed to ensure accurate comparisons across regions of the spectrum and between different sampling and detection arrangements.\(^{20}\) The images that are commonly presented of molecular distribution, based on intensity, can certainly be interpreted on a relative concentration scale.

4.4 Instrument Response Correction

One of the underrated successes of FTRS has been to (re)introduce Raman spectroscopists to the fact that Raman is essentially a single beam technique. This became obvious when comparisons of spectra taken on different FT instruments were made. Relative peak heights were affected by the throughput characteristics of the bench (especially the filter systems employed in
early systems). The solution is to use a calibrated light source as a standard illumination source in the sample position collected under instrument conditions and ratio all subsequent spectra by this standard, analogous to the single beam background used in Fourier transform infrared (FTIR) spectroscopy.

This will then correct for instrument effects, such as long-term drifts in response, as long as conditions are matched between the acquisition of the standard and the sample. Such methodology then allows confident comparison between instruments and also between different optical arrangements on the same instrument. This has obvious advantages and is equally applicable and recommended for CCD–monochromator instrumentation such as is used for Raman microscopy.

5 APPLICATION EXAMPLES

Although it is beyond the scope of this article to review the applications matrix in depth, it is helpful to indicate to some degree the richness of the potential application of Raman microscopy and imaging in academic and “real world” study. This section highlights a few examples of the application of Raman imaging, concentrating on studies of emulsion systems as an example of the level of information content in spectral imaging data sets and how such information can be extracted.

5.1 Polystyrene Spheres – a Raman Image Test Sample

The classic test sample for any Raman microscopy technique is polystyrene spheres. They can be purchased from standard chemical suppliers and have clear optical and spectral signatures which can be detected. Given that they can be observed by both optical and Raman methods, they make an ideal spatial resolution test for a Raman microscope system.

In Figure 7 images of polystyrene spheres of a nominal 3.2-µm diameter are shown. Figure 7(a) is a classical bright field transmission optical microscopy image taken by optical microscopy and Figure 7(b) is a Raman intensity image extracted from the complete spectral image data set obtained by point mapping. The spectral image data set is 77 x 67 pixels at 0.35-µm step size and the Raman image has been created by integrating the intensity of all of the polystyrene bands observed.

5.2 Emulsion Systems

Emulsion systems, given their water-rich nature, are ideally suited to interrogation by Raman microscopy. Figure 8 shows a point microspectroscopic investigation of an emulsion system shown registered to a differential interference contrast optical image. The emulsion has been described in detail in Andrew et al. Such spectra show the presence of spectral (and hence molecular/phase) contrast in the emulsion.

A spectral image of the sample was then obtained by point mapping. Figure 9 shows single wavelength
Figure 9 Single wavenumber intensity images of an emulsion data set. (a) Optical image; (b) 1472 cm$^{-1}$ image; (c) 1720 cm$^{-1}$ image; (d) 1621 cm$^{-1}$ image; (e) 1116 cm$^{-1}$ image; (f) 1308 cm$^{-1}$ image. (Reproduced from J.J. Andrew, T.M. Hancewicz, ‘Rapid Analysis of Raman Image Data Using Two-way Multivariate Curve Resolution’, Appl. Spectrosc., 52(6), 797–807 (1998) by permission of The Society for Applied Spectroscopy.)

spectral intensity images reconstructed from the spectral image data set obtained. These images represent the intensity at a single wavenumber value and, whilst it is clear that there is spectral image contrast observed, the images show a significant amount of noise.

Such images based upon single wavenumber intensity are a poor way of using the spectral image data. In the polystyrene spheres example, integration of several bands was possible to improve the S/N in the image, as there was only one spectral signature in the data set. In the case of multiple component systems where there is much spectral overlap this is not practical. Other more efficient ways of image reconstruction using the information content in the entire spectral image data set are discussed in section 6.

5.3 Other Systems

Many other examples are seen in the literature of all of the approaches to producing Raman images. Indeed, the richness of the applications matrix is immense and, given that reliable, commercially available, hardware has only recently become available, and is not yet installed in many laboratories, it is expected that the number and range of applications can only grow.

Common examples that have been published in the open literature include analysis of carbon,\textsuperscript{49} silicon,\textsuperscript{28,50–52} silicon carbide,\textsuperscript{53} diamond and diamond-like carbon\textsuperscript{54,55} and semiconductors.\textsuperscript{56,57} These examples are widespread not only due to their potential practical application in support of the computer industry but also to the fact that such samples have very favorable Raman scattering characteristics.

Microspectroscopy and Raman imaging have been applied to a wide range of polymer science examples beyond simple polystyrene spheres. Examples can be found in the literature\textsuperscript{22–26,39,45,58–61} these cover model systems (polystyrene spheres embedded in other polymer matrices), defects and inclusions in polymers, real-world mixed polymer systems, and polymer laminates (where confocal detection becomes important).

Raman imaging has found applications in other areas of material science,\textsuperscript{31,62} and in the study of inorganic systems\textsuperscript{63,64} and superconductors.\textsuperscript{65–67}

Biological systems have also been imaged using Raman techniques. These include the in situ study of plant cell wall chemistry\textsuperscript{68–70} and general cell and tissue chemistry in biochemical research, bacterial classification, and cell biology.\textsuperscript{27,71–76} Some attention has also been given to the study of dental adhesive diffusion and dental porcelain in a simulated oral environment.\textsuperscript{77,78}
Although few examples have yet appeared in the peer-reviewed literature, it is clear that the pharmaceutical industry can exploit the capability of Raman microscopy and imaging in understanding the properties of fully formulated products. Potential examples include investigating the association of active materials with excipients, particle size after processing in tablets, and the consequent effects on dissolution and active release. This is in addition to more obvious applications such as identification of contaminants or undesirable actives or polymorphs in both bulk drugs and fully formulated products.

Another field where the potential of Raman microspectroscopy has yet to be fully exploited is the area of forensic science.

6 DATA HANDLING AND DATA ANALYSIS

As has been mentioned above, spectral image data are at a minimum four-dimensional in nature and require some degree of interaction in order to be interpreted.

Specific software tools have been developed by several companies to deal with such data. They all contain essentially the same core features but differ in how interactive the investigator can be with the data set. More recently, it has become clear that the best way to deal with the complexity and to get the best from the enormous amount of information in spectral image data sets is to use sophisticated multivariate analysis techniques to reduce the data to their key elements. These issues are now discussed in more detail.

6.1 Multidimensional Spectral Data Handling and Univariate Analysis

At a bare minimum, software must allow for the generation of specific intensity images at chosen wavenumber (wavelength) and the generation of the full point spectra from each pixel within such an image. The manipulation of images, such as producing an image based upon the relative intensity at two wavenumbers (either by subtraction or division), is useful in dealing with backgrounds which are typically present in Raman images. Similarly, the ability to produce an image based on the integrated intensity under a peak can be used to improve S/N in an image of a particular molecular species. Such functions are usually found as integral parts of the spectrometer acquisition software although some off-line packages do exist for post-analysis of data.

Commonly the user has to define the wavenumber(s) of interest prior to observing the spectral contrast image. This presupposes that the interrogator knows where the interesting spectral contrast information is in the data. A useful variation, of use in complex multicomponent, multiphase systems, is to have the ability to rapidly screen through the spectral image data set for spectral contrast (the equivalent of flicking rapidly through the deck of cards in Figure 1). Often it is observed that spectral contrast occurs in unexpected places in the spectrum and this information is useful in establishing a full understanding of the chemical heterogeneity in the sample.

Raman image reconstruction based upon single wavenumber intensity or ratio of intensities at two wavenumbers is essentially a univariate approach. It is only using a small part of the spectral information that is present in the entire data set to image a particular molecular species. In order to obtain reasonable images which represent the molecular distribution, the univariate approach requires high S/N in each individual pixel spectrum and clear spectral separation of bands which are unique to the molecules or phases of interest. This applies constraints to the complexity of the systems that can be studied and also requires long data collection times for the spectral image data sets.

In most systems, spectral signatures of the individual species will be overlapped and not easily separated and visualized in this way. However, it is clear that changes in signal intensity across the wavenumber range will be observed as you go through the spatial elements of the spectral image data sets and that for each species correlations between intensities at many wavenumber locations will be observed. Therefore a more efficient and elegant approach to use in the analysis of these data sets is multivariate analysis and this is described in the next section.

6.2 Multivariate Analysis

Given the problem of having to analyze very large data sets such as those generated by Raman imaging spectrometers, it is natural that data compression techniques such as principal factor analysis (PFA) (also referred to as principal component analysis (PCA)) would be a reasonable place to begin data analysis. This has been the traditional way of dealing with so much data at one time.

However, the ultimate goal in spectral image analysis should be to extract as much meaningful chemical information as possible in a reasonable period of time. This means generating real or “pure” spectra of individual components or phases in a sample so that a proper chemical identification can be made. And it also means generating real or “pure” concentration or intensity information (maps in the case of image data) for each component so that the quantitative relationship between components is preserved at any spatial location on the sample image.

To move PFA analysis, which produces an abstract mathematical solution to the data reduction, to a
more “real” representation of the data requires a transformation step following PFA that converts the initial estimates of factors and scores into their “real” counterparts. This can be accomplished by applying alternating least-squares (ALS) optimization to the raw factors and scores. The entire optimization process is often referred to as multivariate curve resolution (MCR) based on the curve resolution theory first developed by Lawton and Sylvestre. The MCR process is closely related to other self-modeling algorithms that also use a least-squares transformation to purify variables. However, given the typically large data arrays inherent in spectral image data, a quick and efficient method of analysis is paramount. In such instances, standard curve resolution methods prove to be too time-consuming and therefore impractical for routine application.

The theory of MCR has been thoroughly described in the literature, and it has been demonstrated to be an elegant solution to the problem of the analysis of multidimensional spectral data.

Not only does the MCR data analysis approach lead to the automated generation of score plots, which are equivalent to concentration maps for each phase or chemical component but physically and spectroscopically meaningful factors associated with each score map that can be interpreted with conventional spectroscopic principles. Highly overlapping information

---

Figure 10 Multivariate score plot images of the emulsion data set shown in Figures 8 and 9. Compo, composite; O, orthogonal projection multivariate curve resolution (OPMCR); P, principal factor multivariate curve resolution (PFMCR). (Reproduced from J.J. Andrew, T.T. Hancewicz, ‘Rapid Analysis of Raman Image Data Using Two-way Multivariate Curve Resolution’, Appl. Spectrosc., 52(6), 797–807 (1998) by permission of The Society for Applied Spectroscopy.)
in the spectral dimension can be deresolved taking advantage of the fact that there is contrast in the spatial domain\cite{83} and the spectroscopic interpretation of each factor is greatly simplified over interpreting the images derived from univariate image reconstruction.

Another advantage is that the spectroscopic signal inherent in the data set can effectively be separated from the random noise. This results in higher quality images than could be obtained by the univariate approach, or, alternatively, vastly decreased data acquisition times to obtain the necessary information content in the data set.\cite{83} These two advantages are illustrated in Figures 10–12.

Figure 10 shows score plot images derived by two different multivariate approaches to determining spectral contrast in a spectral image data set.\cite{83} The two approaches, orthogonal projection multivariate curve resolution (OPMCR) and principal factor multivariate curve resolution (PFMCR), are shown to produce equivalent results and both compare favorably with the univariate images shown in Figure 9. The corresponding MCR-generated factors, or spectra, are shown in Figure 11, compared with single spectra extracted from the original data set. Clearly it is valid to interpret the MCR-generated factors by conventional spectroscopic principles.

Figure 12 takes the information generated by the MCR approach for the emulsion system and represents the image data using color coding for the individual phases identified. This is a convenient method of representing the outcome of the MCR analysis.

It is the combined use of these two advantages – speed/automation of data interpretation and tolerance of extremely low S/N – that will make the concept of three-dimensional spatial Raman imaging using hardware confocal/point scanning a practical reality.

7 COMPARISON WITH OTHER MICROSCOPY AND SPECTRAL IMAGING TECHNIQUES

Spectral microscopy in all its forms can be considered to be a subset of microscopy techniques in general, although it is more conventionally thought of as a subset of spectroscopy. The overlap with optical microscopy is becoming increasingly blurred and so a few comments on approaches available within this field follow.

Optical microscopy does provide some molecular information in certain circumstances and indeed absorption
spectroscopy, essentially color contrast, can be used in microscopy as a tool to elucidate the spatial distribution of colored chemical species. Obviously such an approach is limited and the use of phase-specific stains provides a more flexible set of tools to generate contrast in optical microscopy. However, the information obtained is not quantitative and not as specific to the molecular heterogeneity as that obtained by spectral microscopy.

Fluorescence microscopy is usually considered as a subset of optical microscopy due to its wide ranging utility and application in that field. Again specific fluorescent stains for different phases or even macromolecular structures have been developed to allow specific visualization of heterogeneity. Fluorescent tags or labels can be applied to a range of molecules (assuming the synthetic capability is available) and this enables very high sensitivity and specificity for tackling the distribution of single molecular species in complex matrices. Unfortunately, particularly for small molecules, the act of labeling with a fluorescent moiety may change the molecular behavior compared with the untagged system. Also, the expense of labeled molecules (even off-the-shelf, let-alone custom synthesized) prohibits study of large-scale production systems using this approach. Detection of more than one molecule or structure requires multiple label tagging and detection systems, adding to the complexity of sample preparation (although automated detection systems for multiply labeled fluorescent microscopy are now routinely available). Some molecules may be autofluorescent (not requiring labeling to be detected) but this provides a solution in only a few favorable cases and the data obtained may prove to be less easy to interpret.

Spectral microscopy, using the inherent signals of molecules as the contrast element, provides a set of tools to analyze complex mixtures without the need for the complexity of staining, tagging or labeling. Intrinsically it can provide information on all of the molecules in the system in one experiment. The following debate is limited to techniques that fall into this class of methods.

7.1 Other Alternative Approaches to Spectral Microscopy

Raman microscopy has been compared with currently available techniques which can be considered for use in surface and near-surface chemical analysis by Aller. These include electron microprobe (EMP), proton microprobe, IR microscopy, electron microscopy for chemical analysis, energy-dispersive X-ray analysis in electron microscopy, Auger electron spectroscopy, electron energy-loss spectroscopy (EELS), surface ionization mass spectroscopy (SIMS), laser microprobe mass spectrometry (LMMS) and field ion microscopy. The scanning probe microscopies, such as scanning tunneling microscopy and atomic force microscopy and other more recent developments such as scanning near-field optical microscopy (SNOM) and spectroscopic variants of SNOM, including Raman, should also be mentioned in this regard but are currently of limited applicability.

Chemical, structural and distribution information are the primary concerns when choosing a technique to analyze chemical heterogeneity. Chemical analysis can be characterized either by the elemental (atomic) or the molecular information.

Elemental (atomic) analysis is probably the most familiar method employed as the molecular methods, such as the Raman approach presented here, have yet to be as universally established in analytical laboratories, although they have become increasingly common over the last 5 years. Elemental analysis is limited in understanding heterogeneity, particularly in biological or many common chemical systems where there is little elemental contrast. Another limitation is that, of the techniques listed above for elemental analysis, the majority require vacuum sampling.

Molecular identification is far more widely applicable but such information can only be obtained by EELS, SIMS or LMMS – all under vacuum – and by IR and Raman microscopy, which can be performed under ambient conditions. IR and Raman microscopy therefore occupy a unique niche in the analysis of heterogeneity and the comparison between these two close spectroscopic cousins is now made.

7.2 Comparison of Raman and Infrared Microscopy

In microspectroscopy, the IR microspectrometer systems (conventionally referred to as IR microscopes) attached to conventional FTIR benches have undoubtedly proved their worth in the analysis of small quantities of material such as contaminants and inclusions. Essentially they act as microsampling devices for IR spectroscopy and should not be strictly described as IR microscopes using the definitions given in section 2.3. More recently, IR equivalents of both approaches to acquiring a spectral image data set, mapping and image reconstruction and spectral microscopy as described in section 2.3 have been demonstrated.

IR mapping and image reconstruction again uses the obvious sample scanning approach, shown schematically in Figure 3, using a motorized mapping stage to move the sample pixel by pixel through the sampling area of the IR microscope.

The most elegant implementation of IR spectral microscopy does not use the obvious filter approach but instead employs an imaging step-scan FTIR interferometer to collect images of IR intensity at all retardations of the interferometer. Essentially this creates a two-dimensional spectral image data set of spatially resolved
interferograms. For visualization and interpretation of the spectral content, these data are then reorganized into a conventional two-dimensional spectral image data set (see Figure 1) by Fourier transforming the interferograms at each pixel.

In comparing the two vibrational spectroscopic techniques when used to obtain spectral image data, the Raman approach has a number of advantages over the IR. These are as follows:

1. An \(\pm\) spatial resolution of 1 \(\mu\)m. This is an order of magnitude improvement over IR microspectroscopy in the fingerprint region of the spectrum. The limiting factor here is the diffraction limit of the wavelength of light being focused by the microscope. It should be stressed that this applies to “best case” situations. Opaque samples have the potential to “fuzz” the theoretical diffraction limit causing less than optimum spatial resolution.

2. A \(\pm\) resolution of the order of 2 \(\mu\)m. The IR approach mostly requires the absorption signal to be collected in transmission mode and hence the IR imaging data has no depth resolution.

3. Sample preparation. The ease of alignment and interpretation of data in the 180° backscatter arrangement of a Raman microscope requires little sample preparation. Indeed, the sample preparation is often identical to that performed for conventional epi-luminescence microscopy. The use of reflection IR is limited to IR-reflective substrates and even then artifacts are observed in the spectral data. Indeed most IR microscopy experiments have been performed in transmission, which often requires lengthy sample preparation (thin-section microtomy) to produce samples that are able to transmit IR radiation.

4. The ability to study aqueous systems. Water is a weak Raman scatterer but a strong IR absorber. Systems with high water content, such as many biological samples and many industrial products, are not easily analyzed by IR but lend themselves very readily to Raman interrogation.

5. The use of conventional optical microscopes. Raman microscopy at most common excitation wavelengths can be performed on a conventional optical microscopy platform. This enables the sample to be viewed by all of the conventional optical contrast methods and the spectral information registered to these more familiar images. IR microscopy requires a specifically designed microscope employing reflective optics and this restricts you to poor quality bright-field optical microscopy in most cases.

Further comment should be made on the use of reflection IR microscopy. Classical IR microscopy in reflection mode suffers from a depth of interrogation that is highly sample dependent and can only be applied to a limited number of (reflective) samples from which enough IR radiation is reflected to be detected. A potential solution to both of these problems in the point microspectroscopy experiment is to use an attenuated total reflectance (ATR) objective that has been specifically designed to obtain a near-surface spectrum from a small area on a surface. This has been used successfully in obtaining a defined spectrum from surfaces but it is difficult to clearly identify the actual sampled area. The ATR objective requires intimate physical contact between the objective and the surface under investigation and so it is practically most suitable for obtaining a single spectrum. However, one FTIR manufacturer has attempted to automate mapping using the ATR objective and an xyz controlled stage (in order to avoid the necessity for preparation of thin samples to perform IR mapping in transmission) but the ATR mapping approach will always be limited to only a few sample types.

However, it still remains that IR spectroscopy and interpretation is more familiar to most scientists than Raman spectroscopy. Certainly the spectral databases are far more exhaustive and readily available. The nature of the relationship between IR absorption and Raman scattering efficiency will mean that for some molecular systems IR will have a significantly better detection limit and contrast sensitivity than Raman and so the ideal situation is, of course, to have both tools available. However, if there is no clear specific reason for biasing towards IR in the systems under study, when faced with a decision of acquiring either Raman or IR microscopy, currently the argument implies that the choice should be for Raman microscopy first.

### 7.3 Fourier Transform Raman Microprobes

The body of this chapter describes the Raman microscopy technique that has become the de facto standard, that is the use of conventional microscopes, excitation in the region of 780 nm and dispersive spectrographs with CCD detection.

An alternative instrumental approach, at least to point microspectroscopy investigations, is the use of commercially available FT Raman microscopes attached to conventional FT Raman benches. These have been developed by the major FTIR manufacturers as add-on devices to the successful implementation of FTRS as a bulk spectroscopic technique, using the conventional 1064-nm excitation, at high powers to compensate for the decreased Raman scattering
efficiency at the longer wavelength. Not surprisingly, FT Raman microscopes borrow much of their design and technology from FTIR microscopy. There are general points to be made about FT Raman microspectroscopy:

1. The power density required at the sample is a real problem in FT Raman microprobe systems where the energy is tightly focused. This often leads to thermal damage of the sample and thermal background observed in the spectrum; cooling the sample can sometimes help with these effects.

2. The best spatial resolution obtained by commercial instruments that has been reported is 4 \( \mu \text{m} \).\textsuperscript{104} Practically, in most cases spatial resolution will be worse.

3. Absorption of Raman scattered radiation by water in the region of the NIR used for excitation limits the quantitative potential in aqueous media when performing microspectroscopic measurements.

4. Such systems are limited to point mapping if imaging is to be performed.

It can be seen that many of the advantages which Raman microspectroscopy has over IR are brought into question in an FT Raman microprobe and the technique brings added complications primarily as a consequence of the high power density needed to generate adequate S/N. Nevertheless such systems may be a useful investment if you already have an FT Raman system available to you.

A more recent development has been the use of FT Raman with visible wavelength excitation.\textsuperscript{105,106} This approach has been demonstrated as a method to allow low spatial resolution three-dimensional confocal imaging of immiscible liquids in a porous sandstone.\textsuperscript{106} However, due to the problems associated with fluorescence when using visible wavelength excitation, it is not expected that the FT visible confocal Raman approach will be universally adopted.

8 PERSPECTIVE AND FUTURE DEVELOPMENTS

Raman microscopy can be considered to be a technique that has now reached a solid level of maturity. The basic design principles of the microscope systems have reached a de facto standard and the components of the system have been optimized such that the Raman experiment is now, in most cases, shot noise limited. Some subtle differences still remain between the major instrument suppliers but, essentially, investing in Raman microscopy hardware when the study of chemical heterogeneity is important should now be considered relatively risk free.

Any further practical improvement in the methodology is now limited to a few areas. It is likely that we will see a more common adoption of spatial multiplexing. That is, line scanning and spectral microscopy are both particularly applicable where depth resolution is not a concern, such as in surface imaging. The more common adoption of these techniques could well be dependent upon the development of much higher powered lasers in the 780-nm region. At higher power levels, the power density at the sample in the point scanning approach would prove to be a problem and hence the efficiency of distributing that power over a wider area of the sample by spatial multiplexing will become attractive.

It is also expected that further examples of full volumetric three-dimensional Raman imaging will become more common. There are some improvements to be made in more efficient instrument driver software to limit dead time in the data collection process during point mapping. Combined with the use of efficient analysis of low S/N data, such as MCR approaches, it will enable the use of point scanning confocal in three spatial dimensions. Further development of axial deconvolution procedures optimized for the wide-field spectral microscopy approach to three-dimensional imaging will take place.

Perhaps most importantly, software algorithms and rules for the most appropriate methods of data analysis in the study of highly complex, severely spectrally overlapped and high-noise/low-signal systems are being developed.\textsuperscript{79–83} The routine application of these methods to all forms of spectral image data will widely expand the range of systems amenable to study and improve the efficiency of data interpretation.

One limitation of the current approaches to Raman imaging needs further mention. The spatial dimensions of the Raman imaging experiment are constrained at both the low and high ends. The limiting minimum spatial resolution is clearly controlled by the diffraction limit when using a conventional-microscope-based approach to the order of micrometer dimensions. SNOM-based approaches\textsuperscript{97–99} promise to provide Raman images at much improved spatial resolution. However, the light efficiency of such devices limits them to only a few systems of high Raman scattering cross-section.

Perhaps less obviously, there is also a trade-off and limitation at the low spatial resolution/large image size. Essentially, because of the need to maintain high light gathering efficiency, the Raman experiment
is constrained to the use of high numerical aperture objectives. This places a limitation on the best trade-off between spatial resolution and image area covered in the point mapping approach. The sampled area cannot be increased to more than a few micrometers without a serious loss in Raman efficiency. This places a limitation on the maximum step or pixel size when mapping if you are to avoid sub-sampling the area of investigation.

An interesting approach to enable the efficient Raman imaging of large area samples at low spatial resolution is to use imaging fiber bundles.\(^{81,82,107,108}\) These hold some promise in the analysis of samples where large area heterogeneity is important.

**ACKNOWLEDGMENTS**

The author wishes to acknowledge his co-workers in Raman at Unilever Research, in particular Allen Millichope, Ian E. Clark, Tom Hancewicz and Shuliang Zhang. Allen and Ian for those pioneering days in the dark, Tom for showing me the error(s) of my univariate ways and Shuliang for his help with the references used in this work and in taking the Raman technique to new heights. I should also acknowledge Mark Browne at Kinetic Imaging, Liverpool, UK, for assistance with software.

An introduction of the fundamentals of linear and nonlinear Raman spectroscopy is given. The Raman effect

is the result of inelastic light scattering. A small amount of the photon energy of the incident light wave is modulated by the molecular scattering system. An energy transfer occurs as a result of the coupling between the incident radiation and the quantized states of the scattering system. Depending on the coupling, the incident photons either gain or lose energy. The light, which has less energy than the incident laser light, is named Stokes–Raman scattering, and the radiation, which has more energy, is referred to as anti-Stokes–Raman scattering.

In the case of the coupling between strong laser fields and molecular vibrations the observation of nonlinear Raman effects such as hyper-Raman scattering, stimulated Raman scattering (SRS), coherent anti-Stokes–Raman spectroscopy, the Raman gain spectroscopy, etc., is possible.

Apart from theoretical aspects of Raman spectroscopy an introduction into the instrumentation of linear and nonlinear Raman techniques is provided. For linear Raman spectroscopy two alternate approaches are described: dispersive Raman and Fourier transform Raman (FT-Raman) spectroscopy. Special Raman techniques such as micro-Raman spectroscopy and difference Raman scattering are discussed.

In addition, a review of the instrumentation of several nonlinear Raman methods which are based on the second-order ($\chi^{(2)}$) and the third-order nonlinear susceptibility ($\chi^{(3)}$) is given. These methods include coherent anti-Stokes–Raman scattering (CARS), stimulated Raman gain spectroscopy (SRGS), inverse Raman scattering (IRS), photoacoustic Raman spectroscopy (PARS), and ionization-detected stimulated Raman spectroscopy (IDSRS).

1 INTRODUCTION

The Raman effect was first theoretically predicted by A. Smekal in 1923, followed by quantum mechanical descriptions by Kramers and Heisenberg in 1925, and Dirac in 1927. The first experimental evidence for the inelastic scattering of light by molecules such as liquids was observed by Raman and Krishnan in 1928 and almost simultaneously by Landsberg and Mandelstam from solids. After the experimental verification of the Raman effect, the new scattering technique was mainly used for the investigation of organic and inorganic compounds in liquid or solid state or in solution. With the development of the laser in the 1960s and the appropriate detection devices such as multichannel arrays and charge-coupled devices (CCDs cameras), Raman spectroscopy experienced a dramatic growth in analytical applications. Apart from the spectroscopy of phonons,
the Raman effect has been used for studying other quasi particles in solids such as plasmons and polaritons.\(^7\) The development of high intensity laser systems also led to the discovery of several new nonlinear light-scattering processes.\(^8\)–\(^22\)

The Raman effect is the result of inelastic light scattering. A small amount of the photon energy of the incident light wave (nowadays only lasers are used as light sources) is modulated by the molecular scattering system. An energy transfer occurs as a result of the coupling between the incident radiation and the quantized states of the scattering system. Depending on the coupling, the incident photons either gain or lose energy. Since only a small percentage of the incident energy is changed, most of the radiation will have the same frequency after the interaction. The latter is called the elastically scattered light or Rayleigh scattering. The light which has less energy compared to the incident laser light is named Stokes–Raman scattering and the radiation which has larger energy is referred to as anti-Stokes–Raman scattering.

Figure 1 shows a simple model of the scattering mechanism. A photon with the energy \(\hbar \omega_L\) is incident on the scattering system with the energy level \(\hbar \omega_R = E_f - E_i\), where \(i\) and \(f\) label two quantum states. The Stokes–Raman effect results from the transition from the lower energy level \(E_i\) to a higher one \(E_f\). The anti-Stokes effect transfers energy from the system to the incident light wave, which corresponds to the transition from a higher energy level \(E_f\) to a lower one \(E_i\). Since the anti-Stokes scattering occurs from a thermally excited state \(E_f\), which according to Boltzmann statistics is less populated than the ground state \(E_i\), the anti-Stokes intensity is less than the Stokes intensity. Hence, in most cases only the Stokes–Raman spectrum is detected.

The transition observed in Raman spectroscopy from molecules can be between rotational, vibrational or electronic eigenlevels. However, the observation of Raman scattering is in some cases limited by the excitation of fluorescence, which is typically several orders of magnitude stronger than Raman scattering. In solids, Raman scattering can be observed from phonons as well as from other quasi particles.\(^7\) In the following we will primarily discuss Raman scattering from molecules.

2 FUNDAMENTALS OF LINEAR RAMAN SPECTROSCOPY

When light is incident on matter it can interact with the atoms or molecules in different ways. Depending on the energy of the radiation, the photons can be absorbed directly or can be scattered. Absorption of light is most likely if the wavelength of the radiation is in the infrared (IR), visible (VIS) or in the ultraviolet (UV). The IR absorption yields the excitation of rotational and vibrational modes of the molecule, while the UV/VIS absorption results in the excitation of an electronic transition which mostly is followed by fluorescence. Apart from absorption, the incident light can be scattered by atoms and molecules. Investigation of the angular frequency components of the scattered light reveal that most of it is scattered elastically at the same angular frequency. Additionally, there is a small amount of radiation with shifted angular frequency. This

![Figure 1](image-url)

Figure 1 Simple model illustrating Stokes- and anti-Stokes–Raman scattering.
inidentally scattered radiation can occur in the spectrum at lower ($w_S = w_L - w_R$) or higher angular frequencies ($w_{AS} = w_L + w_R$) compared to the excitation angular frequency $w_L$. The scattered light at $w_S$ and $w_{AS}$ is, as already mentioned above, the so-called Stokes- and anti-Stokes–Raman scattering, respectively. The angular frequency $w_R$ corresponds to a rotational or vibrational molecular transition.

Raman spectroscopy is an important method for investigating molecular vibrations. Thus, Raman spectroscopy gives precise information about the chemical structure of molecules and it also can be used to monitor chemical reactions. Since the scattering efficiency of the nonresonant Raman effect is several orders lower than that of fluorescence, the obtained Raman signal is very weak. The introduction of lasers has stimulated this field of molecular spectroscopy in various manners. Combined with the development of new spectrometers and sensitive detectors, Raman spectroscopy experienced a renaissance. New linear (e.g. resonance Raman spectroscopy (RRS), surface-enhanced Raman spectroscopy (SERS), micro-Raman spectroscopy) and nonlinear Raman spectroscopic techniques (e.g. SRS, CARS) have been developed and successfully used in academic and industrial research. Topics covered by Raman spectroscopy include inorganic and organic chemistry, physics, biology, medicine, geology, etc.

In the following section Raman scattering is described by a simple classic treatment, which gives precise information about the location of Raman frequencies as well as first insights into the selection rules of Raman scattering. However, this classical approach can not yield the proper intensity ratio of Stokes to anti-Stokes–Raman bands. Based on the Boltzmann statistics the experimentally determined ratio of the Stokes to the anti-Stokes–Raman intensity can be used for the determination of the spectroscopic temperature of the sample under investigation. The depolarization ratio will be introduced as a quantity which yields information about the symmetry of molecules, randomly oriented such as in liquids.

### 2.1 Classical Treatment of Raman Scattering

Most of the experimental results obtained by Raman spectroscopy can be interpreted by a simple classical theory, because many of the mathematical expressions used are valid under certain conditions even in a quantum mechanical treatment. In this classical approach the molecules are described as an ensemble of atoms performing simple harmonic vibrations, without taking into account the quantization of the rotational and vibrational energy levels.

According to the classical theory, the incident electromagnetic field induces an electric dipole moment of the scattering system (molecule or solid). Such an induced dipole moment is oscillating with the frequency of the incident radiation and is acting as a secondary source for electromagnetic radiation. The light is scattered into a solid angle of $4\pi$. The intensity of the scattered radiation can be deduced from the classical theory.

The incident electric (time-dependent) field vector is given by Equation (1):

$$\vec{E} = \vec{E}_0 \cos w_L t$$

which induces the electric dipole moment $\mu$, as in Equation (2):

$$\mu = \alpha \vec{E}$$

The proportionality quantity $\alpha$ is the polarizability of the scattering system. $\vec{E}_0$ is the amplitude and $w_L$ is the angular frequency of the incident field. $\alpha$ represents a second rank tensor and Equation (2) is the short notation of the following linear equation system given in Equation (3):

\[
\begin{align*}
\mu_x &= \alpha_{xx} E_x + \alpha_{xy} E_y + \alpha_{xz} E_z \\
\mu_y &= \alpha_{yx} E_x + \alpha_{yy} E_y + \alpha_{yz} E_z \\
\mu_z &= \alpha_{zx} E_x + \alpha_{zy} E_y + \alpha_{zz} E_z
\end{align*}
\]

According to these equations, the three components of the electromagnetic field in Cartesian coordinates and the nine components of the polarizability tensor generate three components of the induced dipole moment. $\alpha$ is

![Figure 2](image-url)
in many cases a symmetric matrix, and thus there are only six independent components for most molecules (i.e. \( \alpha_{xx} = \alpha_{yy} \)).

First we consider the easiest case that only one component of \( \vec{E} \) (e.g. \( E_x \)) does contribute to one component of \( \vec{\mu} \) (e.g. \( \mu_x \)). This corresponds to a Raman scattering geometry which is depicted in Figure 2. A water molecule or a crystal is fixed to the \( xz \)-plane of the Cartesian coordinate system. The incident radiation propagates in the \( z \)-direction and is polarized in the \( x \)-direction. According to the interaction of the polarized light wave with the oriented molecule, different dipole components may be excited inside the molecule. The scattered light is observed at \( 90^\circ \) in the \( y \)-direction. Using a polarizer which allows only the observation of \( x \)-polarized light, the observed dipole moment is given in scalar form by Equation (4):

\[
\mu_x = \alpha_{xx} E_x \tag{4}
\]

In a simple short notation, without using any indices, Equation (4) can be written as Equation (5):

\[
\mu = \alpha E \tag{5}
\]

or in combination with Equation (1), it becomes Equation (6):

\[
\mu = \alpha E_0 \cos w_{Lt} \tag{6}
\]

In this case, \( E_0 \) represents the amplitude of electric field component which oscillates in the \( x \)-direction and induces the corresponding dipole moment.

According to the laws of classical electrodynamics an oscillating electric dipole emits radiation of the same frequency at which the dipole oscillates. If the polarizability \( \alpha \) does not change with time (\( \alpha = \text{const.} \)), then the induced dipole will re-emit the incident radiation of the angular frequency \( w_L \) (Rayleigh scattering). However, if the polarizability consists of terms which depend upon vibrational frequencies, these terms will modulate the incident field. According to such time dependent changes in the polarizability \( \alpha = \alpha(t) \) of vibrating molecules, new frequency components will be observed in the scattered radiation. In order to describe a certain lattice vibration or normal mode of a molecule, a harmonic oscillator with the angular frequency \( w_R \) is considered. Its time dependent amplitude is given by Equation (7):

\[
q = q_0 \cos w_{Rt} \tag{7}
\]

In the case that the molecular vibration affects the polarizability and if the vibrational amplitude is small, the polarizability can be expanded in a Taylor series around its equilibrium position \( q = 0 \), to give Equation (8):

\[
\alpha = \alpha(q) = \alpha_0 + \frac{\partial \alpha}{\partial q} q + \cdots \tag{8}
\]

where only terms up to first-order are considered. Introducing Equation (7) in (8), and Equation (8) in (2) results in Equation (9):

\[
\mu = \alpha_0 + \frac{\partial \alpha}{\partial q} q_0 \cos w_{Rt} E_0 \cos w_{Lt} \tag{9}
\]

or, alternatively, Equation (10):

\[
\mu = \alpha E_0 \cos w_{Lt} \tag{5}
\]

\[
\begin{align*}
\text{Rayleigh scattering} \\
+ \frac{1}{2} \frac{\partial \alpha}{\partial q} q_0 E_0 \cos(w_L - w_R) & \\
\text{Stokes--Raman scattering} \\
+ \frac{1}{2} \frac{\partial \alpha}{\partial q} q_0 E_0 \cos(w_L + w_R) & \\
\text{anti-Stokes--Raman scattering}
\end{align*} \tag{10}
\]

According to Equation (10) the scattered radiation of the induced dipole moment consists of three components with the angular frequencies \( w_L \), \( w_L = w_L - w_R \), and \( w_{AS} = w_L + w_R \), which correspond to Rayleigh-, Stokes–Raman, and anti-Stokes–Raman scattering, respectively, as in Equation (11):

\[
\mu = \mu^R + \mu^S + \mu^{AS} \tag{11}
\]

From this simple derivation one can also deduce that \( \mu^S \) and \( \mu^{AS} \) will contribute to the induced dipole moment only if the polarizability does change during the vibration \( (\partial \alpha / \partial q)_0 \neq 0 \). From this we can further draw some conclusion about the Raman activity of a certain vibration. As an example for this the molecule CO\(_2\) is considered. A linear molecule such as CO\(_2\) will have \( 3N - 5 \) normal modes whereas nonlinear molecules will have \( 3N - 6 \) normal modes, where \( N \) indicates the number of atoms in the molecule. Thus, CO\(_2\) has four normal modes, from which two are degenerate. In Figure 3 both the normal modes and the corresponding changes of the polarizability of CO\(_2\) during a vibration are displayed. Only for the symmetric stretching vibration \( v_s \) of CO\(_2\) \( (\partial \alpha / \partial q)_0 \) is nonzero. Therefore, this mode is allowed in Raman scattering. Both other modes, the antisymmetric stretching vibration \( v_{as} \) and the degenerate deformation vibration \( v_{def} \) are not observed in a Raman spectrum because the derivative of the polarizability at \( q = 0 \) vanishes. Those modes are called Raman inactive.

In order to derive an expression for the Raman intensities we consider an oscillating electric dipole with...
angular frequency \( \omega \), in Equation (12),
\[
\mu = \mu_0 \cos \omega t
\]  
where \( \mu_0 \) is the amplitude. The total emitted power derived by classical theory is given by Gerthsen et al.\(^{(24)}\) according to Equation (13):
\[
P = \frac{1}{6\pi\varepsilon_0 c^3} |\ddot{\mu}|^2
\]  
where \( \ddot{\mu} \) is the second derivative of the dipole moment in respect to time, \( P \) is the emitted power, \( \varepsilon_0 \) is the permittivity of vacuum, and \( c \) is the speed of light. Since an optical detector can not resolve optical frequencies in the order of \( \approx 10^{15} \) Hz, an intensity averaged over time will be detected. Using Equation (12) and averaging over time \( (\cos^2 \omega t = 1/2) \) gives the average (over the solid angle of \( 4\pi \)) rate of the total emitted power, as in Equation (14):
\[
\bar{P} = \frac{w^4}{12\pi\varepsilon_0 c^3} \mu_0^2
\]
where \( \bar{P} \) is the total emitted power. Thus, the scattered intensity per solid angle in \( 90^\circ \) direction (such as depicted in Figure 2) yields Equation (15):\(^{(25)}\)
\[
I = \frac{\bar{P}}{8\pi/3} = \frac{w^4}{32\pi^2\varepsilon_0 c^3} \mu_0^2
\]
where \( I \) is the scattered intensity per solid angle in the \( 90^\circ \) direction. Now, consider a dipole \( \mu \) which is located at the origin of a Cartesian coordinate system and does vibrate along a fixed direction. From such an oscillating dipole, a detector which is located in the \( y \)-direction without any polarizer in front, will detect the \( \mu_x \) and \( \mu_z \) but not the \( \mu_y \) component of the scattered intensity, caused by the transverseness of radiation (see also Figure 4), as in Equation (16):
\[
I = \frac{w^4}{32\pi^2\varepsilon_0 c^3} (\mu_x^2 + \mu_z^2)
\]

### 2.1.1 Polarizability

In the same way as an oscillating permanent dipole, an oscillating induced dipole can be treated as a classical electromagnetic emitter. Because of Equation (2) and (3), various components of the induced dipole moment contribute to Raman scattering. First, the different contributions to Raman scattering of molecules with fixed orientation in a Cartesian coordinate system (such as crystals) are considered, followed by randomly oriented molecules (such as gases, liquids, and amorphous solids).

The most common geometry in Raman spectroscopy is a \( 90^\circ \) arrangement (see Figure 5). The incident electromagnetic radiation with electric field vector either
in the x- or y-direction propagates along the z-axis. For both polarization cases the induced dipole moments will consist of three components. Detecting the scattered light in the y-direction allows only the observation of the components \( \mu_x \) and \( \mu_z \), according to Equations (17):

\[
\begin{align*}
\mu_x &= \alpha_{xx} E_x \\
\mu_z &= \alpha_{zz} E_z \\
\mu_y &= \alpha_{xy} E_y
\end{align*}
\]

Therefore, the entire scattering intensity (including the scattered Rayleigh intensity at \( w = w_L \), the Stokes–Raman intensity at \( w = w_s \), and the anti-Stokes–Raman intensity at \( w = w_{as} \)) in the y-direction for x-polarized light is given by Equation (18):

\[
I_{x(x+z)} = \frac{w^4}{32\pi^2\varepsilon_0 c^4} (\mu_x^2 + \mu_z^2) \\
= \frac{w^4}{32\pi^2\varepsilon_0 c^4} (\alpha_{xx}^2 + \alpha_{zz}^2) E_x^2
\]

and for y-polarized light, Equation (19):

\[
I_{y(y+z)} = \frac{w^4}{32\pi^2\varepsilon_0 c^4} (\alpha_{xy}^2 + \alpha_{yy}^2) E_y^2
\]

Using the incident field intensity \( I_0 \) instead of the field amplitudes,\(^{(25)}\) gives Equation (20):

\[
I_0 = \frac{cE_0}{2} E_x = \frac{cE_0}{2} E_y
\]

Combining Equation (20) with Equations (18) and (19) yields Equations (21) and (22):

\[
I_{x(x+z)} = \frac{w^4}{16\pi^2\varepsilon_0 c^4} I_0 (\alpha_{xx}^2 + \alpha_{zz}^2)
\]

\[
I_{y(y+z)} = \frac{w^4}{16\pi^2\varepsilon_0 c^4} I_0 (\alpha_{xy}^2 + \alpha_{yy}^2)
\]

where the first index indicates the polarization of the incident laser beam and the second index characterizes the polarization of the observed scattering. Since in the example above no polarizer was used in the detection line both components (x and z) of the induced dipole are observed. The use of a polarizer in front of the detector results in the suppression of one component, and thus, only one component has to be considered in Equations (21) and (22). In the case of a parallel polarized analyzer in front of the detector Equations (21) and (22) change, as given by Equations (23) and (24):

\[
I_{xx} = \frac{w^4}{16\pi^2\varepsilon_0 c^4} I_0 \alpha_{xx}^2
\]

\[
I_{xy} = \frac{w^4}{16\pi^2\varepsilon_0 c^4} I_0 \alpha_{xy}^2
\]

If a perpendicular polarized analyzer is used the following components of Equations (21) and (22) are observed (Equations 25 and 26):

\[
I_{xz} = \frac{w^4}{16\pi^2\varepsilon_0 c^4} I_0 \alpha_{zx}^2
\]

\[
I_{yz} = \frac{w^4}{16\pi^2\varepsilon_0 c^4} I_0 \alpha_{yz}^2
\]

Analyzing scattered light from a crystal whose main axes have been oriented parallel with respect to the axes of the chosen scattering geometry allows directly the investigation of the different components of the polarizability tensor. Since the main axes of a crystal can be oriented in different ways the Porto notation\(^{(26)}\) has been introduced: \( a(bc)d \), where \( a \) and \( b \) indicate the propagation direction and the polarization of the incident light wave, respectively, and \( d \) and \( c \) characterize the direction of observation and the polarization of the scattered light, respectively. In Figure 6 four examples are given for the measurement of the different tensor components (\( \alpha_{zz}, \alpha_{xz}, \alpha_{zx}, \) and \( \alpha_{yy} \)).

In the following part of this section the Raman scattering of randomly oriented molecules such as gases, liquids, and amorphous solids is discussed. The scattered Raman intensity can be calculated by averaging over all components of every single molecule over the solid angle of \( 4\pi \). In those cases one can not distinguish
Equations (31) and (32): intensity of randomly oriented molecules results then in a constant regardless of the orientation of the molecules.

and second, the anisotropy, as in Equation (28):

\[ \gamma^2 = \frac{1}{2} (\alpha_{xx} - \alpha_{yy})^2 + (\alpha_{yy} - \alpha_{zz})^2 + (\alpha_{zz} - \alpha_{xx})^2 + 6(\alpha_{xy}^2 + \alpha_{yz}^2 + \alpha_{zx}^2) \]  

According to Wilson et al.(28) the averaged squared scattering tensor elements can be written as Equations (29) and (30):

\[ \bar{\alpha}_{xx} = \bar{\alpha}_{yy} = \bar{\alpha}_{zz} = \frac{45\bar{\alpha}^2 + 4\gamma^2}{45} \]  

\[ \bar{\alpha}_{xy} = \bar{\alpha}_{xz} = \bar{\alpha}_{yz} = \frac{\gamma^2}{15} \]  

For a scattering system like in Figure 5 the scattering intensity of randomly oriented molecules results then in Equations (31) and (32):

\[ I_{y(x+z)} = \frac{w^4}{16\pi^2v^2\epsilon^4}I_0N\frac{45\bar{\alpha}^2 + 7\gamma^2}{45} \]  

where \( N \) is the number of molecules in the scattering volume.

2.1.2 Depolarization Ratio

A very useful quantity for the investigation of randomly oriented molecules (gases, liquids, and amorphous solids) is the depolarization ratio \( \rho \). The determination of \( \rho \) yields information about the symmetry of vibrations, which makes easier the assignment of experimentally observed Raman vibrations to normal modes of the molecule. The depolarization ratio \( \rho \) is calculated from the ratio of two intensities, which can be obtained from Raman measurements with different polarization of incident laser light or the scattered light. Analogous to the scattering geometry depicted in Figure 5, where the incident laser beam propagates in the \( z \)-direction and is polarized either in the \( x \)- or \( y \)-direction, the scattered light is observed at 90° in the \( y \)-direction. Depending on the position of a polarizer in front of the detector, the observed dipole moment is either \( x \)- or \( z \)-polarized. This notation can be replaced by using the terms parallel or perpendicular. For example \( I_\parallel (I_\perp) \) indicates that the Raman intensity is measured using a polarizer in front of the detector which is oriented parallel (perpendicular) to the polarization of the incident laser light. The scattering intensity can be obtained by Equations (33) and (34):

\[ I_{xx} := I_\parallel = \frac{w^4}{16\pi^2v^2\epsilon^4}I_0N\frac{45\bar{\alpha}^2 + 4\gamma^2}{45} \]  

\[ I_{yx} := I_\perp = \frac{w^4}{16\pi^2v^2\epsilon^4}I_0N\frac{\gamma^2}{15} \]  

The depolarization ratio is then defined as Equation (35):

\[ \rho = \frac{I_\parallel}{I_\perp} = \frac{3\gamma^2}{45\bar{\alpha}^2 + 4\gamma^2} \]  

Since both components \( \bar{\alpha} \) and \( \gamma \) can be equal to zero, the value of \( \rho \) can vary between 0 and 3/4. A Raman band with \( \rho = 3/4 \) is called depolarized and those with \( 0 \leq \rho < 3/4 \) polarized. Only for totally symmetric vibrations, those which maintain all of the symmetry elements of the molecule, can \( \bar{\alpha} \) be nonzero resulting in a depolarization ratio \( < 3/4 \). All other modes have \( \rho = 3/4 \). Thus, totally symmetric vibrations can be easily distinguished from those which are not.

2.1.3 Anti-Stokes versus Stokes–Raman Scattering

According to Figure 1 and Equation (10), a Raman transition can be either from vibrational/rotational ground
state $i$ to the vibrational/rotational excited state $f$ or vice versa. The first process is known as Stokes transition, whereas the second is the so-called anti-Stokes transition. Thus, a Raman spectrum reveals peaks on both sides of the Rayleigh line having identical frequency shifts. Even though the Raman shifts are identical, the observed intensities are quite different. Since the Stokes process corresponds to an energy transfer from an incident laser photon to a molecule and the anti-Stokes process reveals an energy transfer from a molecule to an incident laser photon, the ratio between the Stokes and anti-Stokes intensity provides information about the population probability of a certain energy state. The population probability is given by the Boltzmann distribution and the intensity ratio can be calculated as given in Equation (36):

$$\frac{I_{AS}}{I_S} = \left(\frac{w_L + w_S}{w_L - w_S}\right)^4 g_v \exp\left(\frac{-\hbar(w_L - w_S)}{kT}\right)$$

where $I_S$ and $I_{AS}$ are the intensities of the Stokes and the anti-Stokes field respectively and $k$ is the Boltzmann constant. $g_v$ is the degeneracy factor of the vibration (rotation). (It should be noted that, in a strict quantum mechanical calculation, where the field is also quantized, the exponent of the angular frequency ratio reduces from 4 to 3.) From Equation (36) we can deduce that the intensity ratio strongly depends on the spectroscopic temperature $T$, and therefore, this ratio can be used for the investigation of the temperature of samples, such as flames.

### 2.2 Short Quantum Mechanical Description of Raman Scattering

A quantum mechanical treatment of Raman spectroscopy is achieved by time-dependent perturbation theory. More easy and for most cases valid is a semi-classical approach. The results of the semi-classical treatment will be presented in the following. Further, the selection rules will be revisited according to the quantum mechanical description as well as to group theory considerations.

In quantum mechanics the scattering system is not considered as a system consisting of atoms performing harmonic vibrations, but rather as vibrations which are quantized. The allowed energy level of each vibration is given by Equation (37)

$$E_v = \hbar w \left(v + \frac{1}{2}\right)$$

where $w$ is the angular frequency of the vibration and $v$ is the vibrational quantum number. A full approach of treating Raman scattering by quantum mechanics is obtained by time-dependent perturbation theory. However, such a treatment is not very simple and most often not necessary. In a semi-classical approach the classical treatment of the dipole oscillation is combined with the quantum mechanical treatment of the scattering system and its changes during a vibration. Under certain conditions, which are fulfilled for most of the molecules and crystals, the polarizability tensor can be replaced by its quantum mechanical analog. This can be concluded if the dipole moment of the transition $f \leftarrow i$ is considered compared with Equation (2), to give Equation (38):

$$\mu_{ji} = \int_{-\infty}^{+\infty} \psi_f^* \mu \psi_i \, dr = \langle \psi_f | \mu | \psi_i \rangle$$

$\psi_f$ and $\psi_i$ denote the wave function of the initial and the final quantum state, respectively. In spontaneous Raman scattering the initial quantum state is for example a vibrational ground state, and the final quantum state is an excited vibrational state. The components of the polarizability tensor in Equations (18), (19), (21), and (22) can be replaced by the matrix elements given in Equation (39):

$$\langle \alpha_{\rho \sigma} \rangle_f = \langle \psi_f | \alpha_{\rho \sigma} | \psi_i \rangle$$

Placzek showed further that spatial averaging over squares of the matrix elements $\langle \alpha_{\rho \sigma} \rangle_f$ results in the same values as if averaging over the squares of the components of the polarizability tensor $\langle \alpha_{\rho \sigma}^2 \rangle_f$ is performed. Thus, the Equations (18), (19), (21), (22) and Equation (35) are still valid for this semi-classical approach.

#### 2.2.1 Selection Rules for Raman Scattering According to the Quantum Mechanical Description as well as to Group Theory Considerations

In order to learn something about the selection rules in Raman spectroscopy we have to consider Equation (39) once more. A transition $f \leftarrow i$ is allowed if just one of the six matrix elements $\langle \alpha_{\rho \sigma} \rangle_f$ with $\rho = xx, yy, zz, xy, xz, yz$, is nonzero. Thus, there are six integrals to be calculated in order to determine whether a matrix element is nonzero or not. However, group theory will provide the same information, but with less effort. To get started on this issue, we first consider how symmetry operations of a certain point group affect the components of the polarizability tensor. In Figure 7 the used scattering geometry is depicted, which is essentially the same as in Figure 5. A water molecule has a fixed orientation in the center of the coordinate system. In this figure also all symmetry operations of the point group $mm2 = C_{2v}$ of water are displayed. Depending on the chosen polarization of both the incident light wave $\vec{E}$ and dipole moment $\mu$ four components of the polarizability tensor $\alpha_{xx}, \alpha_{xz}, \alpha_{xx},$ and $\alpha_{xy}$ (see Equation 17) contribute to the Raman scattering in this scattering geometry.

To evaluate, for example, the transformation behavior of the tensor component $\alpha_{zz}$ one needs to consider...
the irreducible representation of \( B_1 \). Similarly, this is also which transforms as the function \( zx \).

Thus, it belongs to the totally symmetric representation or is contained to the first excited vibrational state \( f \). As a result, that a certain integral in range between \( \sigma \) and \( \mu \) needs also to be totally symmetric. The latter will be fulfilled if \( \alpha_{i\rho} \) and the wave function of the first excited vibrational state \( \psi_f \) belong to the same symmetry class, that is, the application of all symmetry operations of the point group transforms in the same way.

Whether there are Raman active vibrations or not in a certain point group can be easily seen by considering the “character tables”. Consider, for example, the naphthalene molecule which belongs to the \( mmm \) point group (notation according to Hermann–Mauguin) or to the \( D_{2h} \) point group (notation according to Schönflies). Raman active vibrations are only expected from the irreducible representations \( A_u, B_{1u}, B_{2g}, \) and \( B_{3g} \), because these transform as the functions \( x^2, y^2, z^2(A_g), xy(B_{1g}), xz(B_{2g}), \) and \( yz(B_{3g}) \), respectively. Raman transitions in the irreducible representations of \( A_u, B_{1u}, B_{2u}, \) and \( B_{3u} \) are forbidden.

### 2.3 Enhancing Raman Signals

The classical spontaneous Raman scattering is an appropriate analytical tool in order to investigate the qualitative as well as the quantitative composition of gases, liquids, or solids. However, there are serious drawbacks which have to be dealt with when using techniques based on spontaneous Raman scattering. First, the conversion efficiency of the Raman effect is poor. Only a portion of \( 10^{-6} \) to \( 10^{-8} \) laser photons are converted into Raman photons, limiting the detection of molecules with very low concentration. Second, certain molecular systems, such as fluorophores exhibit high fluorescence quantum yields and even weak fluorescence signals may be strong enough to mask the Raman signals.

Therefore, much scientific effort was invested in developing Raman based techniques, which allow the above mentioned problems to be overcome. The next two chapters deal with two approaches, the resonance Raman effect (RRE) and SERS, with which the Raman intensity can be enhanced by orders of magnitude and/or fluorescence can be quenched.

#### 2.3.1 Resonance Raman Effect

Until now, the energy of the excitation source was considered to be far away from an electronic transition, corresponding to major simplification of Raman theory. The relevant expression for the Raman intensity in the resonance case has been derived by Kramers and Heisenberg\(^2\) and Dirac\(^3\) from second-order, time-dependent perturbation theory and further developed by Albrecht.\(^30\) Since Raman scattering is a two-photon process, the first step is the virtual absorption of an

incident photon from the initial state $i$ to the entire manifold of eigenstates of the unperturbed molecule, followed by the second step, the virtual emission to the final state $f$. The components of the transition polarizability tensor are calculated by a summation over all unperturbed eigenstates of the resonant electronic state,\(^{(31)}\) according to Equation (40):

$$
(\alpha_{\rho\alpha})_p = \sum_r \left\{ \frac{\langle f|\mu_r|r \rangle \langle r|\mu_i|i \rangle}{\hbar w_i - \hbar w_L - i\Gamma_r} + \frac{\langle f|\mu_r|r \rangle \langle r|\mu_f|i \rangle}{\hbar w_f + \hbar w_L - i\Gamma_r} \right\}
$$

(40)

where $\langle f|\mu_r|r \rangle$ corresponds to the $r$th component of the transition dipole moment associated with the transition $f \leftarrow r$. $\mu_r$ is the dipole moment operator in the $\rho$ direction. The suffixes $\rho$ and $\alpha$ refer to the molecule-fixed Cartesian vector $x$, $y$, and $z$. $w_L$ and $w_i$ are the angular frequencies of the incident radiation and the angular frequency associated with the transition from the initial state $i$ of the Raman transition to any state $r$ of the unperturbed molecule, respectively. $\Gamma_r$ is the damping factor related to the lifetime of the state $r$. Note, that the summation is over all states $r$ of the unperturbed system, with the exclusion of $i$ and $f$, the states between which the Raman transition takes place.

The scattered RR intensity can be calculated with a semi-classical approach similar to section 2.2. The total intensity scattered on the average into a solid angle semi-classical approach similar to section 2.2. The total transition takes place.

$$
I_R = C |I_0(w_L \pm w_R)|^4 \sum_{\rho,\alpha} |(\alpha_{\rho\alpha})_p|^2
$$

(41)

Here, $w_L$ and $w_R$ are the angular frequency of the incident laser radiation and the angular frequency for Raman transition from state $i$ to state $f$, respectively. $I_0$ denotes the incident laser intensity and $C$ is constant which depends on the unit system used.

Two types of RREs can be distinguished: the pre-RRE and the rigorous RRE. In Figure 8, the conventional Raman effect (a), the pre-RRE (b), and the rigorous RRE (c) are depicted. Far away from an electronic absorption, all terms in the denominator and the numerator of the Raman intensity expression such as $w_{el} - w_L$, which depend on the electronic state with the angular frequency $w_{el}$ are negligible (see Equation 40). However, when the photon energy of the exciting laser beam approaches the energy of an electronic transition those terms dominate the observed Raman intensity and thus, the obtained Raman spectrum. In general, the closer the excitation energy approaches the electronic resonance condition, the greater is the intensity of the observed Raman spectrum. Typically, the pre-RRE is observed when the exciting laser angular frequency comes within the high or low angular frequency wing but not under the observable vibrational structure of the electronic absorption band in the Raman scattering process. When the exciting laser angular frequency actually falls within the observable vibrational structure, then the rigorous RRE is observed. In the case that the angular frequency is getting close to an electronic transition, the first term of Equation (40) begins to dominate, and the polarizability as well as the Raman intensity will be dominated by the resonant excited state.

RRS is of great interest in the case of large polyatomic molecules, such as biological molecules, where the absorption is often localized in a particular group of a large molecule, which is the so-called chromophore. The RR enhancement permits the isolation of the Raman bands of a chromophore and structural units located close to it, and therefore gives information about sites of a molecule, which makes an assignment of complicated molecules possible.

Apart from the Raman intensities, the selection rules are also affected under resonance condition. Certain transitions normally forbidden in conventional Raman scattering are allowed in resonance Raman scattering. Those changes provide further information about the molecular system under investigation.

Since the angular frequencies of Raman vibrations depend on the electronic ground state, whereas the scattered Raman intensity is dependent on the absolute location of the incident laser energy to the electronic absorption, information about properties of a molecule in an electronic excited state can be obtained from RRS. The measurement of the scattered Raman intensity as a function of the incident laser energy produces the so-called excitation profile (EP), from which the strength of the interaction between the electronic excited state and the vibrational mode can be estimated.

The change in the selection rules as well as an enhancement of the observed Raman intensity by up to six orders of magnitude give rise to various applications of both pre-RRS and rigorous RRS in chemistry, biochemistry, and biology as well as in physics. For utilizing the RRE no special equipment other than that used for conventional Raman spectroscopy is necessary.
However, it may be suitable to use a tunable laser as excitation source, which allows an appropriate adjustment of the excitation energy lying in the electronic absorption. For example, with the excitation in the UV the minimal detectable concentration of certain species can be lowered by orders of magnitude of five to six using the RRE. For more information on RRS we refer to several reviews.\(^{32}\)

2.3.2 Surface-enhanced Raman Scattering

The second effect which gives rise to an enhancement of Raman signals by up to six orders of magnitude or even more was discovered in the mid-1970s, and is referred to as surface-enhanced Raman scattering. Fleischmann et al.\(^{33}\) discovered that molecules adsorbed on an electrochemically roughened silver surface give dramatically enhanced Raman signals. Recently, other metals, such as copper or gold, also showed enhanced Raman spectra under certain conditions. Efforts are made for even single molecule detection by means of SERS.\(^{34–36}\)

Until now, there is no complete theoretical understanding of this surface enhancement. Different groups contributed to the surface enhancement problem.\(^{37–39}\) In the following, only a brief discussion about the possible enhancement mechanisms will be given. From normal Raman scattering it is well known (see Equation 2), that the transition dipole moment \(\mu\), which a molecule experiences, depends on the transition polarizability, \(\alpha\), and the strength of the electric field, \(E\). Therefore, molecules located close to a silver surface can experience either an enhanced electric field or a modified polarizability. According to this distinction the surface theory is divided into two classes: the “electromagnetic field” enhancement mechanism, in which the field experienced by the adsorbate molecule is larger than it would be far from the surface, and the “molecular” enhancement mechanism, in which \(\alpha\) is perturbed by interactions of the adsorbate with the surface.

Classical electromagnetic theory based on the solution of Maxwell’s equations indicates that molecules adsorbed to a metal surface will experience a large increase in the electromagnetic field strength compared to the strength of the incident radiation. The extent of the electromagnetic enhancement depends on a number of factors, including the electric properties of the metal, the distance of the molecule from the surface, the orientation of the molecule with respect to the normal of the surface, the energy of the incident radiation, the morphology of the surface, and the size and the geometry of surface roughness. Of particular importance is the surface roughness or curvature, which can be obtained electrochemically or by the use of sols or island films. Calculations showed that the interaction of a light field with a flat (smooth) metal surface can enhance the Raman intensity scattered by an adsorbed molecule by a factor of six.\(^{39}\) An intensity enhancement of \(10^4\) to \(10^7\) can be obtained using roughened metal surfaces, such as small metal particles or rough surfaces of conductive materials. On irradiating rough surfaces, which are usually approximated in theoretical models\(^{40}\) by isolated spheres or spheroids, with light, the incident electromagnetic field can excite an oscillation of conduction electrons inside the metal. Due to this dipole oscillation the particles become polarized, and start emitting a secondary electric field. Thus, the field at the particle surface is the superposition of the incident field and the generated secondary fields. Since the conduction electrons are spatially confined, they have a characteristic frequency known as the plasma frequency. The quantized state of these plasma oscillations is called a plasmon. If the frequency of the incident field is resonant to such a plasma resonance of the metal, the generated secondary fields become significantly large, and thus a molecule adsorbed on the surface will experience a large enhanced electromagnetic field. The strength of the field enhancement falls off as \(1/r^3\) away from the surface and strongly depends on the extent of the curvature of the particle. The frequency of a plasma resonance depends on the metal, on the particle size as well as on the particle shape. Only roughened or particular metals such as silver, copper, or gold can be used as substrate in SERS technology, because only their plasma frequencies are lying in the VIS range or the near IR range of the electromagnetic spectrum.

The transition polarizability \(\alpha\) can also be altered as a result of electronic interaction between the adsorbate and the metal. Such an enhancement can be obtained by a direct charge transfer between molecule and metal, excitation of electron–hole pairs requiring atomic scale roughness, or the formation of a chemical bond between the adsorbed molecule and the metal, and are limited to molecules in the first monolayer, being in direct contact with the metal surface. Thus, mechanisms which are modifying \(\alpha\), are the so-called short-range enhancements.

The selection rules for SERS are essentially the same as those for conventional Raman spectroscopy. However, because the local field at the surface is highest in the direction normal to the surface, vibrational modes involving changes in the adsorbate polarizability perpendicular to the surface are preferentially enhanced. A detailed summary of the selection rules for SERS has been given by Creighton et al.\(^{38}\) The normal direction of the electric field plus the fact that the electromagnetic amplitude falls off rapidly with the distance from the surface allows one to determine the adsorbate orientation with respect to the average surface normal as well as the proximity of the adsorbate functional groups to the surface.
In general a SERS setup is essentially the same one as used for conventional Raman spectroscopy. However, to optimize the electromagnetic surface enhancement effect the used laser frequency has to match the frequency of a plasma resonance. Since the enhancement effect strongly depends on the physical properties of the substrate, a large variety of different types of substrates are presented in the literature. The most common substrates are electrodes, sols, metal films, and silver metal island films. Because SERS provides both rich spectroscopic information and high sensitivity as a result of the large enhancement effect, it is an ideal tool for trace analysis as well as for in situ investigations of various interfacial processes. The method has been applied for the study of a variety of molecules from diatomic ones to molecules of biological importance. Various reviews on SERS have been written to which we refer the interested reader.\(^\text{(32)}\)

### 3 FUNDAMENTALS OF NONLINEAR RAMAN SPECTROSCOPY

The introduction of lasers, especially of pulsed laser systems (e.g. Nd: \(\text{YAG}\) (neodymium: yttrium aluminum garnet) laser), has given rise to the development of several new nonlinear optical effects. In 1961 Franken et al.\(^\text{(41)}\) demonstrated the possibility of second harmonic generation, and Kaiser and Garrett\(^\text{(42)}\) observed the two photon absorption. The coupling between strong laser fields and molecular vibrations permit the observation of nonlinear Raman effects such as hyper-Raman scattering,\(^\text{(27)}\) SRS,\(^\text{(8, 9)}\) CARS,\(^\text{(27)}\) the Raman gain spectroscopy,\(^\text{(10)}\) the inverse Raman effect,\(^\text{(11)}\) the Raman-induced Kerr effect (RIKE),\(^\text{(12)}\) and the PARS.\(^\text{(13)}\)

The interaction of strong incident laser fields with molecular vibrations can result in an elongation of the electron shell which does not obey Hooke’s law any more. Therefore, the induced polarization consists of a linear and a nonlinear contribution. Generally the induced dipole moment \(\mathbf{p}\) in a molecular system is written in the form given in Equation (42):

\[
\mathbf{p} = \alpha \mathbf{E} + \frac{1}{2} \beta \mathbf{E} \cdot \mathbf{E} + \frac{1}{6} \gamma \mathbf{E} \cdot \mathbf{E} \cdot \mathbf{E} + \cdots \tag{42}
\]

where \(\alpha\) is the linear polarizability, \(\beta\) the hyperpolarizability, and \(\gamma\) the second order polarizability. The \(\alpha, \beta,\)
\(\gamma\) etc. are tensors of rank 2, 3, 4, etc, respectively. \(\mathbf{E}\)
is the electric field, \(\mathbf{E} \cdot \mathbf{E}\) is the dyadic product of two electric fields, etc. The nonlinear terms of Equation (42) are usually small compared to the linear term, which gives rise to normal, linear Raman scattering. However, when the electric field is sufficiently large, as is the case when for instance a Q-switched laser is focused on the sample, contributions from the second term in Equation (42) are sufficiently intense to be detected.

#### 3.1 Spontaneous Nonlinear Raman Scattering: Hyper-Raman Effect

The importance of the hyper-Raman effect, which stems from the second order term of Equation (42), as a spectroscopic tool results from the fact that it allows the observation of modes, which are accessible neither by IR nor by Raman spectroscopy. Since its discovery by Terhune et al.\(^\text{(14)}\) in 1965, hyper-Raman spectra have been observed in all three states of aggregate. However, reasonable signal-to-noise ratios could only be obtained after the development of high repetitive, high-power lasers and highly sensitive detectors (multichannel diode arrays or CCDs).

The hyper-Raman effect is a three-photon process involving two virtual states of the scattering system. The level scheme for hyper-Rayleigh and hyper-Raman scattering is presented in Figure 9. Two laser photons of the angular frequency \(w_L\) are simultaneously scattered to give a photon at angular frequency \(2w_L - w_R\) (Stokes hyper-Raman) or \(2w_L + w_R\) (anti-Stokes hyper-Raman) when a molecular vibration (or rotation) is excited or destroyed, respectively. Thus, hyper-Raman lines are found in the spectral neighborhood of \(2w_L\) (the second harmonic) of the incident laser radiation. It should be mentioned that Rayleigh scattering always occurs, but hyper-Rayleigh scattering occurs only if the scattering material does not have a centre of symmetry. Frequency-doubled radiation consists of hyper-Rayleigh scattering from a pure crystal and consequently a crystal used for frequency doubling must not have a centrosymmetric unit cell.

![Figure 9 Schematic level diagram for hyper-Rayleigh and hyper-Raman scattering.](image-url)
The importance of the hyper-Raman effect as a spectroscopic tool results from its selection rules. These are determined by products of three dipole moment matrix elements relating the four levels indicated in Figure 9. It turns out that all IR active modes of the scattering system are also hyper-Raman active. In addition, the hyper-Raman effect allows the observation of “silent” modes, which are accessible neither by IR nor by linear Raman spectroscopy. Hyper-Raman spectra have been observed for the gaseous, liquid and solid state. A full description of the theory and practice of hyper-Raman spectroscopy is given by Long.\(^{(15,27)}\)

### 3.2 Stimulated Raman Scattering

At high laser intensities the Raman scattering can become so intense that the Stokes radiation can also influence the molecules. Thus, the molecules interact with two fields: the laser field at angular frequency \(\omega_L\) and the Stokes field at the angular frequency \(\omega_S = \omega_L - \omega_R\). Both fields couple with each other at the angular frequency \(\omega_R\) of the vibrating molecule. According to this parametric coupling, laser energy can efficiently be transferred into the Stokes–Raman field and/or the anti-Stokes–Raman field resulting in the development of an intense SRS signal. Above the threshold about 20 to 30\% of the incident laser radiation can be converted into SRS. The major disadvantage of SRS is that only the Raman modes with the highest gain can reach the threshold, and therefore, an SRS spectrum yields less molecular information than spontaneous Raman scattering does. However, this disadvantage can be turned into an advantage by using SRS as a monochromatic, coherent light source for special wavelength ranges.

Both linear Raman scattering and hyper-Raman scattering are spontaneous inelastic light scattering processes. The incident radiation excites with a certain probability one possible molecular vibration in one molecule. Since the vibrational excitation is totally stochastic, common Raman or hyper-Raman spectra are the result of the superposition of stochastic totally independent vibrations from individual molecules.

To obtain coherent molecular vibrations within a certain macroscopic area (e.g. inside the focus area of the laser beam), meaning those molecules are vibrating with a constant phase relation, an intense laser radiation has to be used. Such a process is called SRS. In general, the Raman effect is a very weak process. Its intensity can be sufficiently enhanced by both the RRE and the SERS, as shown above. However, there is another effective way to enhance the strength of Raman signals, which is schematically depicted in Figure 10 and explained as follows. Spontaneous Raman emission depends in a linear way on the input laser intensity. Thus, an intense input laser field will lead to an intense Stokes field \((n\omega_S)\), where \(n\) is the number of Stokes photons), which can stimulate the emission of further Stokes photons, if it is incident on a molecule simultaneously with a laser field at angular frequency \(\omega_L\). While the incident light beam loses a quantum \((\hbar\omega_L)\) and the molecule is excited by a quantum \((\hbar\omega_R = \hbar(\omega_L - \omega_S))\), a quantum \((\hbar\omega_S)\) is added to the wave at frequency \(\omega_S\), which consequently becomes amplified. Thus, SRS is a self-amplifying process which is observed in a forward and backward direction of the incident laser pulse. In contrast to spontaneous Raman emission, the conversion efficiency can be about 20 to 30\% of the incident radiation. In the case that the generated SRS wave, which is also called first-order SRS, at \(\omega_{1S} = \omega_L - \omega_R\) is intense enough and can serve as pump source for another first-order SRS process, multimode SRS at \(\omega_{1S} = \omega_L - \ell\omega_R\) is observed. This process is illustrated in Figure 11.

A theoretical description of the stimulated Raman effect in terms of nonlinear Raman susceptibility was presented by Bloembergen\(^{(16)}\) soon after the experimental discovery of this effect. He showed that a polarization at Stokes angular frequency \(\omega_S\) is generated via the third-order nonlinear susceptibility \(\chi^{(3)}\). Including a degeneracy...

![Figure 10](image1)

\[ \omega_L, \omega_S, (n+1)\omega_S \]

\[ \omega_{LS}, \omega_{RS}, \epsilon \]

**Figure 10** Schematic level diagram for SRS as a quantum process.

![Figure 11](image2)

\[ \omega_{LS}, \omega_{LS} - \omega_R, \omega_{LS} - 2\omega_R, \omega_{LS} - 3\omega_R \]

\[ \eta_0L, \eta_0S, \eta_02S, \eta_03S, \eta_0R, \eta_02R, \eta_03R \]

**Figure 11** Multimode SRS: first-order SRS \((\omega_{LS})\) is pumped by the laser \((\omega_L)\); second-order SRS \((\omega_{LS})\) is pumped by the laser like first-order SRS radiation; third-order SRS \((\omega_{3S})\) is pumped by the laser like second-order SRS radiation.
factor, the polarization oscillating at angular frequency \(w_S\) is given by Berger et al.\(^{17}\) (Equation 43):

\[
\vec{P}^{(3)}(w_S) = \frac{6}{4} \varepsilon_0 \chi^{(3)} (-w_S; w_L, -w_L, w_S) [\vec{E}(w_L)]^2 \vec{E}(w_S)
\]  

(43)

For the case that the pump angular frequency \(w_L\) and the Stokes angular frequency \(w_S\) differ by a molecular angular eigenfrequency \(w_R\), i.e., \(w_L - w_S = w_R\), the third order nonlinear susceptibility has a negative imaginary part. This leads to a negative absorption coefficient or an exponential gain at the Stokes frequency \(w_S\) proportional to laser intensity at pump frequency\(^{19}\) \(w_L\).

The exponential growth has been shown to depend on the differential Raman cross-section \(d\sigma/d\Omega\) (\(\Omega = \text{solid angle}\)) as well as on the linewidth \(\Gamma\) of the molecular transition \((w_R)\) in Equation (44)\(^{18}\):

\[
g(w_S) \propto \left( \frac{d\sigma}{d\Omega} \right) \frac{\Gamma}{(w_L - w_S - w_R)^2 + \Gamma^2}
\]  

(44)

Optimum gain is found at the center of the Raman line where \(w_R = w_L - w_S\). There the gain constant for SRS at Stokes frequency is given by Equation (45):

\[
g_S \propto \left( \frac{d\sigma}{d\Omega} \right) \frac{1}{\Gamma}
\]  

(45)

From Equation (45) we can immediately recognize that in SRS processes where only one input laser field with frequency \(w_L\) is employed, a coherent Stokes wave is generated for those Raman modes which have highest ratio between differential Raman cross-section and linewidth \(\Gamma\). The latter corresponds to the dephasing time \(T_2\) of the physical system, \(\Gamma = 1/T_2\), and reflects the damping of the system. Because of this limitation to modes having the highest ratio between differential Raman cross-section and linewidth and an exponential dependency of the Stokes intensity on the incident laser intensity, SRS as an analytical tool for detailed qualified and quantified information from a sample in an optical cell is not as suitable as spontaneous Raman scattering. However, this disadvantage can be turned into an advantage by using SRS as a monochromatic, coherent light source for special wavelength ranges.

In the classical description of SRS a coherent light beam at Stokes angular frequency \(w_S\) is produced by the pump field at \(w_L = w_S + w_R\). The distinctive feature of SRS is that an assemblage of coherently driven molecular vibrations provide the means of coupling the two light waves at angular frequency \(w_L\) and \(w_S\) by modulating the nonlinear susceptibility.

In ordinary Raman scattering the Stokes scattering is generally accompanied by anti-Stokes scattering. Since only a few molecules are found in the vibrational excited state at room temperature, the anti-Stokes–Raman intensity is weak. The strong pumping action of the laser beam changes this situation drastically, so that an appreciable fraction of all molecules in the laser beam are soon available for the anti-Stokes emission. Classically, the anti-Stokes radiation is generated by the interaction of the laser beam with molecular vibration, but the phase of the latter is established by the still more intense Stokes radiation. This is a four-wave mixing process, which is called stimulated anti-Stokes–Raman scattering.

Since a pair of laser photons is converted into a Stokes photon and an anti-Stokes photon, no momentum is transferred to the sample. The initial and the final state of this process are identical, therefore, the next two laser photons can be converted in the same molecule without any relaxation time. Thus, the conversion efficiency is high.

As a consequence, an index-matching requirement exists for this four-wave process. The direction of the emission of the anti-Stokes intensity is given by the momentum matching condition\(^{18}\) Equation (46)

\[
\vec{k}_{AS} = 2\vec{k}_L - \vec{k}_S
\]  

(46)

Since, in condensed phases, there is dispersion of the linear index of radiation, \(n = n(w)\) and because Equation (47) holds,

\[
|k| = \frac{n(w)w}{c}
\]  

(47)

one immediately recognizes that a collinear arrangement between pump, Stokes and anti-Stokes beams is not possible. However, a direction can be found which satisfies the vector Equation (46), but it confines the S and \(AS\) photon pair to conical beams coaxial with the laser beam. Figure 12 shows the required construction, the cones being generated by rotating the plane of the figure around \(\vec{k}_L\).

The interaction of the electric fields of two input laser beams with angular frequencies \(w_L\) and \(w_S\) with the electric field associated with coherent molecular vibrations can yield also a gain or a loss in the power of the laser beams. The method where the gain at Stokes frequency is measured is generally referred to as SRGS, whereas the inverse Raman scattering (IRS)

![Figure 12 Momentum conservation for stimulated anti-Stokes Raman scattering (representation of Equation 46).](image-url)
is the terminology used to designate the induced loss at the pump laser frequency. IRS is also often called stimulated Raman loss spectroscopy (SRLS). In Figure 13 a schematic diagram for a few techniques in nonlinear (coherent) Raman spectroscopy is displayed.

Esherick and Owyoung\(^{43}\) have developed a double-resonance method called IDSRS. This technique combines the high sensitivity of resonant laser ionization methods with the advantages of stimulated Raman spectroscopy, e.g. the high spectral resolution. The excitation process, illustrated in Figure 14, can be briefly described as a two-step photoexcitation process followed by ion/electron detection. In the first step two intense narrow-band lasers \((\omega_L, \omega_P)\) are used to pump a molecule from its ground state, \((a)\), to a vibrationally excited level, \((b)\), via the stimulated Raman process. The vibrationally excited molecules are then selectively ionized in a second step via a two-photon process by a laser tuned to be resonant with the electronic state, \((c)\), in the molecule. The technique allows an increase in sensitivity of over three orders of magnitude because ions can be detected with higher sensitivity than photons. This technique has become very important when femtosecond lasers are used (see section 3.4). Of all nonlinear Raman spectroscopic techniques CARS is the most often applied. Although a lot of experimental effort is necessary to utilize CARS, the advantages, especially the high CARS intensities, the high spectral and spatial resolution, and the capability of rejecting fluorescence makes CARS a very valuable spectroscopic tool.

The applied laser power of pump and Stokes laser in a typical CARS experiment is in the range \(10^4 – 10^5\) W; the produced CARS signal output power can be up to 1 W, whereas the output power in conventional Raman spectroscopy is in the range of \(10^{-4}\) W. In addition the CARS signal is directional with a small solid angle while spontaneous Raman photons are emitted at a solid angle of \(4\pi\). The collection angle range is up to five orders of magnitude larger in conventional Raman spectroscopy. Taken together, these two factors imply that CARS is nine orders of magnitude less sensitive to sample fluorescence than spontaneous scattering. The advantage is actually even greater since the CARS signal is at higher frequency than any of the input laser frequencies.

### 3.3 Coherent Anti-Stokes–Raman Scattering

As shown in the section before a high power laser pulse interacting with matter can excite coherently driven molecular vibrations in conjunction with the generation of an intense coherent Stokes beam. However, only signals from a Raman active mode having the highest gain factor will give rise to stimulated Raman emission. Thus, for molecular spectroscopy with which all Raman active modes should be investigated in order to obtain information about the chemical and structural composition of the sample molecules, excitation with one single strong laser field would certainly not serve the purpose, because only from one particular mode an intense signal will be observed.

This drawback can be avoided when an intense Stokes field is applied externally to the sample by a second laser. In a CARS experiment one laser operates at angular frequency \(\omega_L\) and the second laser at the angular frequency \(\omega_S\). If the frequency difference between both laser fields coincides with the frequency of a molecular vibration \(\omega_R = \omega_L - \omega_S\), a strong coupling of the incident laser field, the Stokes field, and the field generated by the coherently driven molecular vibration via the third order

---

**Figure 13** Schematic diagram for a few techniques in nonlinear (coherent) Raman spectroscopy; CSRS, coherent Stokes–Raman scattering; SRGS, IRS; (= SRLS); CARS; PARS.

**Figure 14** Energy-level diagram illustrating the two excitation steps of IDSRS.
nonlinear susceptibility is observed. However, even if the frequency difference does not match a molecular vibration this CARS process can occur, albeit with reduced intensity. The energies for both four-wave mixing processes are illustrated in Figure 15, (a) displays the resonant CARS process, whereas (b) corresponds to the non-resonant CARS process, which always occurs if \( w_L - w_S \neq w_R \). Although the resonant CARS process dominates the CARS spectrum it is usually seen against a background emission due to the parametric coupling of the nonresonant process.

According to Figure 15(a) in the first step a vibrational quantum \( \hbar w_R \) is generated by the two quanta \( \hbar w_L \) and \( \hbar w_S \), as given in Equation (48)

\[
\hbar w_R = \hbar w_L - \hbar w_S \quad \text{(48)}
\]

In the second step the vibrational quantum \( \hbar w_R \) is destroyed again by the two quanta \( \hbar w_L \) and \( \hbar w_{AS} \), given by Equation (49)

\[
-\hbar w_R = \hbar w_L - \hbar w_{AS} \quad \text{(49)}
\]

The energy conservation of this process is given by Equation (50):

\[
\hbar w_{AS} = 2\hbar w_L - \hbar w_S \quad \text{(50)}
\]

As shown in section 3.2 using Equations (46) and (47) an anti-Stokes signal \( w_{AS} \) is generated only, when the momentum matching condition is fulfilled. In the case of gases, where the dispersion of the index of refraction \( n = n(w) \) is negligible, collinear arrangement between pump and Stokes laser beam is sufficient. In condensed phases, however, a slight angle between pump and Stokes beam is required. In contrast to SRS, where the coherent signal is generated with only one input laser beam \( w_L \), the anti-Stokes intensity is not scattered into a cone as described above. Instead, it is scattered in one direction, which lies in the plane given by the two laser beam directions \( \vec{k}_L \) and \( \vec{k}_S \) and which is determined by the momentum vector diagram shown in Figure 12. A common CARS experiment can be performed by keeping one of the two lasers, e.g. the laser with the angular frequency \( w_L \) fixed in frequency and the other one, e.g. the laser at Stokes angular frequency \( w_S \) tunable. The coherent anti-Stokes signals are generated each time the frequency difference of the input laser fields matches the molecular frequency of a Raman active transition. Since the CARS signal occurs blue shifted compared to the Rayleigh line, excited fluorescence can not mask the CARS spectrum because of its red shift.

The intensity of generated anti-Stokes radiation can be calculated according to Equation (51)

\[
I_{AS} = \frac{w_{AS}^2}{n_1 n_2 n_{AS}^2 \epsilon_0 c^4} \chi^{(3)}_{CARS}( L^2 I_L I_S L^2 \sin^2 \frac{\Delta k L}{2} \quad \text{(51)}
\]

where \( n_i \) is the refractive index at the angular frequency \( \omega_i \) (i = L, S, AS), \( I_L \) and \( I_S \) are the intensities of the incident pump and Stokes laser beams, respectively, \( L \) is the length over which the beams are mixed through the sample (interaction length), and \( \Delta k \) is the wave vector mismatch, i.e. \( \Delta k = |\vec{k}_L - \vec{k}_S - \vec{k}_{AS}| \). \( \Delta k \) is a direct result of the fact that the propagating waves move in and out of phase because of dispersion in the sample. The dependence of \( I_{AS} \), on the square of the CARS susceptibility is characteristic for parametric processes. \( \chi^{(3)}_{CARS} \) can be directly related to the differential Raman cross-section \( d\sigma/d\Omega \) as well as to the number density \( N \). We finally note that the phase matching factor in the CARS intensity, i.e. the \( \text{sinc}(x) = \sin(x)/x \) function is essentially unity under most experimental conditions, which are usually chosen such that \( \Delta k = 0 \) for maximum signal.

In order to obtain a large angular separation of the generated CARS beam from the input laser beams, Eckbreth(44) introduced a new beam arrangement, the so-called BOXCARS geometry which still obeys the phase-matching condition. In Figure 16 the phase matching is displayed. In this approach the \( w_L \) pump beam is split
Figure 16 Phase matching for BOXCARS.

into two nonparallel components, which together with the Stokes beam are focused under a larger angle $\theta_i$ into the sample. According to Figure 16, the geometry formed by the wave vectors $\vec{k}_L$, $\vec{k}_S$, and $\vec{k}_{AS}$ correspond to a "box". From this the name BOXCARS is derived. Note, for the BOXCARS arrangement the laser beams need not reside in the same plane. The phase-matching can also be fulfilled when the two pump beams $w_L$ lie in one plane, and the $w_S$ beam lies in another one (see Figure 17). This type of beam arrangement is known as Folded-BOXCARS and reveals the great advantage that the anti-Stokes beam is completely spatially separated from the incident wave mixing components. However, the disadvantage of this beam arrangement is the small spatial overlap of the laser beams.

In the following we discuss the major advantages but also the limits of CARS. First, in contrast to linear Raman spectroscopy, in a usual CARS experiment the intensity of the CARS signal is four to five orders of magnitude more intense. Thus, in CARS spectroscopy there is in general no detection problem caused by too little intensity if the number density $N$ of the molecules is high enough. Second, the CARS signal occurs as an intense signal beam, which can be discriminated from light resulting from other processes (e.g. fluorescence) even with collinear beam arrangement using filters and a large distance between sample and detector, because the intensity of fluorescence decreases with $1/r^2$. If condensed material is under investigation, the CARS beam can even be separated spatially (as shown above). Third, the CARS process is performed by lasers, which can spatially be focused onto a small region of some micrometer in radius. Thus, the signal is produced only in a small area of the sample which has two consequences: (1) CARS spectroscopy exerts high spatial resolution, and (2) small sample quantities in the range of some micrograms can be investigated easily. Fourth, CARS spectroscopy reveals a high spectral resolution, because, in principle, no spectrometer is necessary in front of the detector. Thus, the spectral resolution is limited by the linewidth of the used laser systems. Fifth, CARS is used for low concentration determination. In the case of non-resonant CARS, meaning that none of the energies of the two lasers hit an electronic resonance, the detection limit is in the range of 0.01 to 0.05 M. However, when the excited virtual states coincide with electronic eigenstates of the molecule, a resonance enhancement of the CARS signal is found. Such a process is referred to as resonance CARS and concentrations in the range $10^{-5}$ to $10^{-7}$ M can be detected. Sixth, fluorescence of the sample can not mask the CARS signal.

However, CARS can only be performed with high experimental effort. In order to carry out a CARS experiment, it is necessary to avoid any signal fluctuation caused by intensity and frequency instabilities of the lasers, or due to changes of the spatial overlap of excitation laser beams.

Until now, the four-wave mixing process was performed using the three frequencies $w_L$, $w_L$, and $w_S$, which leads to the generation of a fourth wave with the angular frequency $w_{AS}$. Analogous to the above mentioned coupling the three frequencies $w_S$, $w_S$, and $w_L$ also can mix, generating a new wave at the angular frequency, according to Equation (52)

$$2w_S - w_L = w_S - (w_L - w_S) = w_S - w_R$$

The signal is produced with a shift of $w_R$ on the Stokes side of the $w_S$ line. This type of scattering process is referred to as CSRS. This technique tends to overlap with fluorescence, and furthermore, the CSRS signal is, in principle, weaker than CARS signals. Thus, CARS is used more frequently.

3.4 Femtosecond Time-resolved Nonlinear Raman Scattering

Ultrafast molecular vibrations and rotations are the fundamental motions that characterize chemical bonding and determination of the reaction dynamics at the molecular level. The time scale for these motions are typically 100 fs for vibrations and 100 ps for rotations.
Recent advances in time–domain spectroscopy have enabled spectroscopists to capture chemical processes directly on the time scale of the fastest elementary steps.\(^{1,46,47}\)

The investigation of the time-resolved propagation of chemical reactions experienced a tremendous progress within the last two decades. Molecular vibrations and rotations are the fundamental movements in describing chemical bonding and molecular reaction dynamics. The dynamic of a chemical bonding of a molecular system is on a time scale from some femtoseconds to several picoseconds. The development of femtosecond laser systems allows the investigation of physical and chemical processes in real time, revealing deep insight into dynamics of chemical reactions. The fundamental concept of femtosecond laser spectroscopy is based on the generation of molecular wave packets and its observation in real time. Since the pulse time is so short one can coherently excite many vibrational modes at a time. The superposition of these stationary eigenstates is known as a wave packet. The time-dependent development of such a wave packet can be investigated by probing the system with another time-delayed ultra-short laser pulse.\(^{1,46,47}\)

Ultrashort laser pulses with a duration of less than about 100 fs allow for a coherent broadband excitation with preparation and detection of vibrational superposition states. The time evolution of these generated wave packets in the ground and the electronically excited state give information on the molecular dynamics. There are different possibilities for studying the molecular dynamics in real time. Typically, the linear response of the optical field in a two-pulse pump-probe scheme is used in order to initiate and probe the wave packets in a certain quantum state.\(^{46–48}\) In such experiments, the signal detection is performed by laser-induced fluorescence (LIF),\(^{49–51}\) absorption,\(^{52,53}\) resonant impulsive stimulated Raman scattering (RISRS),\(^{54}\) multiphoton ionization (MPI),\(^{55}\) and by several other methods such as, for example, femtosecond up conversion.\(^{56}\)

The high intensity of femtosecond laser pulses enables the application of nonlinear spectroscopic techniques such as CARS or CSRS for the investigation of molecular systems. The first results of fs time-resolved CARS of liquids were presented by Leonhard et al.\(^{57}\) in 1987. The principle of this technique is depicted in Figure 18 using iodine vapor as an example of gaseous matter. Three laser fields, two at angular frequency \(\omega_L\) (pump laser) and one at angular frequency \(\omega_S\) (Stokes laser), are interacting with the molecules. The pump laser has to overlap with vibrational and rotational eigenstates of an electronic excited state of the molecule and the Stokes wave has to be chosen such that the difference of the \(\omega_L\) and \(\omega_S\) matches

![Figure 18](image-url)

**Figure 18** Illustration of the principles of femtosecond-time-resolved CARS spectroscopy. (a) Potential energy-level diagram of iodine with the four wave interaction; (b) spatial arrangement of the four waves; (c) temporal pulse pattern.
an angular frequency $w_R$ of a Raman active vibrational mode. Using delay lines between the three pulses different type dynamics of the molecules under investigation can be probed.\(^{58}\) In the case that first one pump pulse interacts with the matter, a wave packet is generated in the electronic excited state. If the two other laser pulses at $w_L$ and at $w_S$ enter the sample with a certain time delay (in the fs to ps time range, $\Delta t < 0$) the CARS transient is revealing the dynamic of the electronic excited state (see Figure 18c). However, when one pump and the Stokes pulse simultaneously interact with the sample a wave packet in the electronic ground state is prepared. Thus the delayed pump ($\Delta t > 0$) generates a CARS transient from which the vibrational and rotational dynamic of the ground state can be deduced (see Figure 18c).

In the same way other techniques such as degenerate four-wave mixing (DFWM) or CSRS have been successfully applied.\(^{59}\)

4 INSTRUMENTATION FOR LINEAR RAMAN SCATTERING

In modern Raman instrumentation there are two alternate approaches: first, the dispersive Raman spectroscopy, and second, the FT–Raman spectroscopy. Both techniques are described in the next two parts of this section. Finally, in the last part, special Raman techniques such as micro-Raman spectroscopy and difference Raman spectroscopy will be discussed.

4.1 Dispersive Raman Spectroscopy

Considering the necessary parts of an experimental Raman setup (see Figure 19) the following components are required to perform a Raman experiment: (1) a light source for the excitation of Raman scattering, (2) a collection optics to collect the Raman scattered light, (3) a monochromator, i.e. a dispersing optical element to separate Raman scattered light into its wavelength components, (4) a detection system to measure the relative intensity of the Raman scattered light. In this section the different parts of a Raman setup will be briefly reviewed. Readers interested in more details are referred to several review articles and book chapters.\(^{60,61}\)

4.1.1 Light Sources

In the mid-1960s there was a renaissance in conventional Raman spectroscopy by simply replacing the existing light sources (e.g. mercury lamps) by lasers. In general, radiation can be emitted by atoms, ions, or molecules which are in an excited state either spontaneously or the transition from the excited state to the ground state can be stimulated by another photon. The latter occurs only if a photon of the same frequency interacts with the matter. Laser action is the result of the stimulated emission process which is giving rise to certain properties of this kind of light source, as follows.

- The outgoing laser photons produce a narrow, and essentially parallel beam, usually with a Gaussian intensity profile.
- The emitted waves are coherent, i.e. being in phase, unlike spontaneous light sources.
- Except for broad-band lasers, laser light is monochromatic.
- The parallel laser light can be easily focused using a lens. The focusing allows the recording of Raman spectra with high spatial resolution (see the micro-Raman spectroscopy section 4.3). However, there is a natural limit in focusing laser light which is called the diffraction limit.
- Apart from continuous wave (CW) lasers pulsed laser systems are also available. In general such a laser first accumulates energy as a population inversion is built up. Using a Q-switch enables the release of the accumulated energy through the emission of a single laser pulse which is usually very short.
- The laser light is usually polarized which results from the construction of the cavity.

In the following paragraph, a short overview of laser light sources used for Raman spectroscopy is given. First, one has to distinguish between CW and pulsed laser systems, and second, there are lasers with a fixed wavelength and those with a tunable wavelength range. For analytical linear Raman spectroscopy mostly CW lasers with fixed wavelength are applied. In the last two decades the argon and the krypton ion laser were used in many Raman laboratories. Enabled by the development of very sensitive micro-Raman setups...
the He–Ne laser has also been used as light source for Raman spectroscopy. However, even at the same irradiance Raman spectra obtained from an argon ion laser at 514 nm will be 2.3 to 4.5 times more intense as Raman spectra obtained from a He : Ne laser operating at 633 nm. Such an \( w^4 \) dependence of the Raman intensity on the laser wavelength can be understood by considering Equations (33) and (34), where \( w_S = w_L - w_R \). Recently, red diode lasers as well as CW Nd : YAG lasers have been used in micro-Raman spectroscopy. In particular, the investigation of biological material such as plant cells, living tissue, needs a light source with a wavelength in the near IR to avoid the excitation of fluorescence. For resonance Raman investigation laser lines in the UV are necessary. Such UV lines are provided for example by an argon ion laser (e.g. 351 and 363 nm or the frequency doubled lines at 244 and 257 nm) or pulsed laser systems such as SRS, CARS. The Nd : YAG with its fundamental laser at 1064 nm is a powerful, stable light source, which in addition is very reliable. To use the Nd : YAG laser in the VIS region it is necessary to double its frequency. Usually addition is very reliable. To use the Nd : YAG laser in the UV a quartz prism has to be used. Second, a spherical, microscope objective, or a cylindrical lens is used to focus the parallel laser beam onto the sample. Those lenses may be coated in order to reduce the reflectance of the laser light. Since the Raman intensity is proportional to the irradiance, which is the ratio of the laser power to the area of cross-section, focusing of the laser light increases the obtained Raman signals. However, high irradiance may cause damage to the sample. The minimum beam waist by focusing is fundamentally given by the diffraction limit. Dependent on the used wavelength of the laser, \( \lambda \), the outgoing laser beam diameter, \( D \), and the focal length of the lens, \( f \), the beam waist, \( d \), can be approximated by Equation (53):\(^{27}\)

\[
d = \frac{4\lambda f}{\pi D} \tag{53}
\]

Third, to record Raman spectra, the optimal choice of collection optics is important. Usually the collection system consists of two lenses (see Figure 20). According to Equation (54) the recorded Raman intensity depends on the solid angle over which the scattered light is collected.

\[
I_s \propto d\Omega \tag{54}
\]

In order to collect the largest possible solid angle a lens with a high aperture (up to 1 : 0.75) has to be used. The second lens focuses the collected light onto the entrance slit of the spectrometer. To ensure that the spectrometer is not overfilled or underfilled the lens has to match the \( f \) number of the spectrometer. The collected Raman intensity can be doubled by using a spherical mirror as depicted in Figure 20.

In general, in Raman spectroscopy two scattering geometries are most common. The scattered light can be collected at 90\(^\circ\) or at 180\(^\circ\) (back-scattering) to the
incident laser beam. Instead of single lenses it is also very common to use camera objectives for the light collection.

### 4.1.3 Monochromator

For dispersing the collected light a monochromator is required. Since the generated Raman intensity is about six orders of magnitude weaker than the Rayleigh intensity, a monochromator has to discriminate efficiently the Rayleigh radiation. In Raman spectroscopy, single, double as well as triple monochromators using one, two, or three gratings, respectively, are well established.

Until the development of multichannel detectors (OMA, CCD) the scanning Czerny–Turner double monochromator or additive spectrometers with a photomultiplier as detector were most often applied. The stray light in these instruments is discriminated by two gratings with an intermediate slit. Nowadays the standard configuration is either a triple monochromator or a single monochromator in combination with sharp-cut filters, such as a multilayer dielectric interference filter or diffraction filter. In a triple monochromator the first two stages (subtractive mode) are used for Rayleigh stray light rejection, whereas the third monochromator, the so-called spectrograph, disperses the collected Raman radiation onto a multichannel detector. The advantage of such a device is that the Raman spectrum can be recorded very close (within a few wavenumbers) to the Rayleigh line. The drawback is the poor light transmittance. However, if high light throughput and collection efficiency is required, rather than measuring close to the excitation line, a single grating monochromator with a notch filter will be the appropriate choice.

### 4.1.4 Detector

The collected radiation is recorded using a detector, which transforms the input radiation into an output signal. The latter can be an electric charge, a current, or a potential. The ratio between output and input of a detector is defined as the responsivity of the detector. One distinguishes between single-channel and multichannel detectors. The most important single-channel detector is the photomultiplier. The physical base of this device is the photoelectric effect. The amplification of the incident photon signal is typical of $10^6$ to $10^7$ in such a photomultiplier.

In modern Raman setups the photomultiplier tube is replaced by multichannel detector devices. The most common multichannel detectors are intensified diode arrays and CCDs. Both detectors reveal the multiplex advantage, meaning that a large spectral range can be detected simultaneously. Typical intensified diode arrays comprise up to 1024 individual diodes, whereas CCDs are two-dimensional arrays of pixels (e.g. $512 \times 1024$).

### 4.1.5 Sample Preparation

For Raman excitation of liquids and solids, there is usually no special sample preparation necessary. If the measurements are performed in the VIS excitation range ordinary glass capillaries can be used. Also, substances dissolved in water can be investigated in glass capillaries by Raman spectroscopy without any further preparation. This is because water as well as glass reveals only very weak Raman signals. For the investigation of gases it is common to use multi-pass cells, in order to increase the Raman intensity. However, if resonance Raman experiments are carried out in the UV, the glass has to be replaced by quartz. Light-absorbing samples have to be treated with more care in order to avoid thermal decomposition. Kiefer and coworkers have developed several experimental arrangements for the investigation of solids as well as liquids using spinning cell techniques.

### 4.2 Fourier Transform Raman Spectroscopy

In general, routine Raman spectroscopy of highly absorbing samples is associated with two problems. First, the excited fluorescence masks the Raman scattering because it is several orders of magnitude more intense. Second, the absorption of light very often causes a thermal decomposition of the sample. Often the fluorescence is caused by impurities and not by the sample itself. Most biological samples fluorescence when illuminated with VIS laser light.

These problems can be circumvented by using a near-IR wavelength for Raman excitation. In this spectral range the electronic transitions from the electronic ground state occur infrequently, which avoids excitation of fluorescence. Furthermore, the photochemical decomposition of the samples is reduced because of the low photon energy in the near-IR. However, this spectral range is
due to the $w^4$ dependence of the Raman cross-section unfavorable for Raman spectroscopy. As an example, the sensitivity of a Raman experiment is reduced by a factor of 18 when changing the excitation wavelength from the 514 nm line of an argon ion laser to the 1064 nm line of a Nd:YAG laser.

Excitation in the near-IR together with FT-Raman spectroscopy overcame the problems of fluorescence, thermal and photochemical decomposition. Furthermore, the use of interferometric optics give rise for achieving multiplex measurements, partially compensating the $w^4$ dependence. Pioneering work in FT-Raman spectroscopy has been performed by Hirschfeld and Chase in 1986 and Chase in 1987 and several other groups have been active in this field since then.

A conventional FT-Raman setup is composed of a light source, the collection optics, an interferometer, and a detector. A scheme of a FT-Raman apparatus and the sample holder is displayed in Figure 21. Usually a CW Nd:YAG laser operating at 1064 nm is used as light source. The single-mode output power lies between 10 mW and 10 W. The laser beam is focused onto the sample with a spot size of approx. 100 µm. The scattered light is collected by an aspherical lens either under 90° or 180° backscattering geometry (see panel (b) of Figure 21). A “notch” filter is used to remove the laser line from the collected light. The light is directed into the interferometer which is optimized for the near IR range. The detection is performed with a liquid-nitrogen-cooled germanium or room-temperature InGaAs detector. Usually, a fast Fourier transform (FFT) algorithm transforms the interferogram into a power density spectrum. The resolution of an FT-Raman spectrum is dependent on the distance $x$ the moving mirror travels and the apodization factor used in transforming the spectrum. In an FT-Raman setup the entrance slit is replaced by a spherical pin-hole causing a much higher light throughput (Jacquinot advantage) than is possible in a conventional dispersive Raman spectrometer.

4.3 Special Raman Techniques

4.3.1 Micro-Raman Spectroscopy

Nowadays the technique of micro-Raman spectroscopy is a very well established method for both the investigation of micro-samples in the order of picograms or even less and the spectroscopic imaging of the sample surfaces.\(^{68}\) One of the first micro-Raman setups has been described by Hirschfeld.\(^{69}\) The author combined an optical microscope with a Raman setup. A scheme of a typical micro-Raman setup is displayed in Figure 22. A microscope objective serves both to focus the laser beam on the sample and to collect the scattered light. Microscope objectives with high numerical aperture and high magnification are used to focus the light to the diffraction limit. The 514 nm line of an argon ion laser can be focused to a spot of about 1 \(\mu m\). In many cases the focused laser spot produces high-power density typically in the range between 10\(^4\) and 10\(^8\) W cm\(^{-2}\). For Raman spectroscopy of microscopic samples various techniques have been developed (e.g. the rotating sample technique\(^ {70}\) or surface scanning Raman microscopy\(^ {71}\)) in order to avoid heating and decomposition of sensitive, especially absorbing samples. For the investigation of fluorescent micro-samples such as dyes and biological cells, the FT-Raman spectroscopy with long wavelength excitation is also available in combination with a microscope.

4.3.2 Difference Raman Spectroscopy

Raman difference spectroscopy involves simultaneous (or nearly simultaneous) recording of Raman signals from two different samples. This is accomplished by rotating the split cell\(^ {72}\) at the rate of about 1000 – 2000 rpm. Thus the Raman scattered signals originating from the two compartments of the split cell are alternately detected. After appropriate signal matching, one signal is subtracted from the other resulting in the difference spectrum. This technique can thus be used to examine solute bands without solvent interference, for example, by subtracting the solvent bands from those of the solution. Although it appears that this kind of technique only emulates the double-beam technique already known in IR spectroscopy, the RDS technique has an added advantage and offers a unique application in that it can be used to measure accurately wavenumber shifts or linewidth changes, especially when they are quite small.

The simultaneous recording of two (or more) signals increases remarkably the accuracy of the Raman data. This is primarily because several experimental errors such as reproducibility (backlash) error of the spectrometer from one scan to another, power variation of the exciting laser line with time, adjustment instabilities due to temperature effects, and fluctuations in the response function of the electronic detection system are almost eliminated by applying this technique.\(^ {72–76}\)

Beside the advantages mentioned above, the simultaneous recording of two Raman signals offers several other possibilities. The Raman signals, for instance, from two different polarization measurements can be compared with each other and this permits a direct recording of depolarization ratio\(^ {77}\) or the purely isotropic part\(^ {78}\) of the Raman scattered light, taking a linear combination \((I_1 - 4I_3I_\perp)\), as a function of wavenumber. In another application, by using circularly polarized light,\(^ {79}\) the circular intensity differential or the reversal coefficient can be recorded in a single scan; a detailed description of all aspects has been given by Kiefer\(^ {64}\) and Asthana and Kiefer.\(^ {80}\)

Considering the above mentioned types of RDS techniques it would be desirable to simultaneously record both the \(I_1\) and the \(I_\perp\) from two different samples and it will obviously permit to combine the advantages of difference Raman studies and polarization measurements into one. In order to achieve it, a four-channel gated photon counting system was developed by Eichele et al.\(^ {81}\) which allowed simultaneous recording of four different signals as well as the linear combinations with desired coefficients. Based on this detection system, Laane and Kiefer developed the technique of four-channel Raman difference spectroscopy (FC-RDS).\(^ {82}\) With the advent of multichannel detectors two new concepts for RDS were introduced. Kamogawa and Kitagawa\(^ {83}\) used branched bundles of optical fibers to collect the Raman signals of two samples simultaneously on different rows of the CCD detector. A combination of the established rotating split cell scheme and multichannel detection was introduced by Deckert et al.\(^ {84}\) Here a setup with rotating blinds was used to measure distinct samples. To further increase the accuracy the latter scheme also utilizes the scanning multichannel technique.\(^ {85, 86}\)

A very sophisticated technique in RDS was introduced by Martin.\(^ {87}\) He kept the sample fixed and used a rotating mirror device. This offers some unique possibilities, such as comparing crystals, gels, and fibers to water solution, all of the same material. Another advantage is the analysis of as little as 10 \(\mu L\) of scarce sample material. The backscattering RDS technique has been introduced by Eng et al.\(^ {88}\) A multisample system for RDS has been constructed by Savoie et al.\(^ {89}\)

5 INSTRUMENTATION FOR NONLINEAR RAMAN SCATTERING

A review of the instrumentation of several nonlinear Raman methods which are based on the second-order
Hyper-Raman scattering signals are typically five to seven orders of magnitude weaker than those of linear Raman scattering. Larger hyper-Raman signals are produced under resonance conditions \(^{(90,91)}\) and in surface-enhanced hyper-Raman scattering.\(^{(92–94)}\) Since hyper-Raman scattering is an incoherent process which does not require phase matching, it is preferentially observed at an angle of 90° from the incident laser direction. As for any spontaneous phenomenon, a double monochromator is used in most cases. Initial hyper-Raman spectra were generated with a Q-switched ruby laser operating at \(\approx 1\) Hz\(^{(14)}\) and detected with a synchronously gated photomultiplier tube and subsequently with optical multichannel detection.\(^{(95–97)}\) The use of CW pumped acousto-optically Q-switched Nd: YAG lasers (repetition rates of 5 kHz), synchronously gated photomultiplier tubes,\(^{(98,99)}\) and synchronously gated two-dimensional single photon counting detectors\(^{(100,101)}\) has improved the signal-to-noise ratio of hyper-Raman spectra. Considerable further improvements have been obtained with mode-locked pulses (at 82 MHz) from a Nd: YAG laser to observe the surface-enhanced hyper-Raman signal from pyridine adsorbed on silver.\(^{(93)}\) In these studies hyper-Raman signals were observed with intensities close to spontaneous Raman scattering. They showed that SEHRS has become a useful spectroscopic technique. In view of the recent advances in laser and detector technology, significant improvement in SEHRS sensitivity will come rapidly from the use of intensified CCD cameras for hyper-Raman signal detection and the use of a continuously tunable mode-locked Ti:sapphire laser as the excitation source.\(^{(102)}\)

5.2 Coherent Anti-Stokes–Raman Scattering

CARS is the most widely practiced nonlinear Raman spectroscopy technique.\(^{(103)}\) The major experimental advantage of CARS (and of most nonlinear coherent Raman techniques) is the large signal produced. In a typical CARS experiment in a liquid or a solid, the applied laser power of the pump and Stokes laser \(\left(10^4 - 10^6\right) W\) generate an output power up to \(1\) W,\(^{(20)}\) while conventional Raman scattering would give a collected signal power of \(\approx 10^{-4} W\) with the same lasers. Since the CARS output is directional, the collection angle can be five orders of magnitude smaller than that needed in spontaneous scattering. Taken together, these two factors imply that CARS is nine orders of magnitude less sensitive to sample fluorescence than spontaneous scattering. The advantage is actually even greater since the CARS signal is at a higher frequency than any of the input laser frequencies. However, there are some disadvantages of CARS: (1) an unavoidable electronic background nonlinearity that alters the line shape and can limit the detection sensitivity; (2) a signal that scales as the square of the spontaneous scattering signal (and as the cube of the laser power), see Equation (51), making the signals from weakly scattering samples difficult to detect; and (3) the need to fulfill the phase matching requirement of section 3.3. While other techniques avoid these difficulties, CARS still remains the most popular coherent nonlinear technique.

There are several experimental possibilities for carrying out CARS. Some of the most practical ones will be discussed next.

5.2.1 Scanning Pulsed Coherent Anti-Stokes–Raman Scattering

A typical CARS device for condensed phase spectroscopy which has been developed at the University of Würzburg\(^{(104)}\) is shown in Figure 23. Because it contains two tunable \((w_L, w_S)\) laser sources it is also suitable for performing resonance CARS spectroscopy in liquids or in solids.\(^{(105–108)}\) For the simultaneous pumping of the two dye lasers a pulsed (10 Hz) Nd: YAG laser with a harmonic generator and a prism harmonic beam separator (Spectra Physics Quanta Ray models GCR-4, HG-4 and PHS-1, respectively) are used. The third harmonic of the Nd: YAG laser with wavelength at 355 nm is split into two beams by a 2:1 beam splitter (BS1 in Figure 23). These beams are then used to pump the two dye lasers. They supply the pump \((w_L)\) and Stokes \((w_S)\) beam respectively. The outputs of the dye lasers are corrected for divergence by lenses (L1 and L2) with long focal length. Dye luminescence of the pump laser is removed by a linear dispersing prism arrangement (PR) followed by an aperture (A1). The output of the dye lasers can be chosen to be horizontally or vertically polarized. To achieve exact polarization conditions Glan–Thompson polarizers (P1, P2) are added. The polarization of the Stokes beam can be turned separately by means of a double Fresnel rhombus (FR). The two laser beams are crossed and focused on the sample by an achromatic lens (AL1). The crossing angle can be tuned by changing the distance of the two parallel laser beams. The latter is achieved by moving the phase conditioning mirror (M4) in the way indicated in Figure 23. The CARS signal \(w_{AS}\) which is generated in the sample under a certain angle is made parallel to pump and Stokes beam after passing an achromatic lens (AL2). Moving mirror M5 in the direction indicated in Figure 23 while tuning the Stokes laser wavelength leads to a compensation of the change of the observation angle.
It is important to have the CARS beam in a final fixed position for further rigorous separation from the two dye laser beams. Part of the latter is performed by apertures (A2 and A3). After passing an analyzer (P3), a shutter (S) and a further aperture (A4), the CARS beam is finally focused (by L3) on the entrance slit of a double monochromator (Spex 1403) which suppresses remaining laser or stray light.

For the purpose of alignment a He:Ne laser is installed which fixes the optical axis of the double monochromator. The signal path is aligned along this axis. When the Stokes laser frequency is tuned, mirrors (M4 and M5) are simultaneously moved under computer control to compensate for dispersion (phase-matching).

The monochromator can be calibrated by means of several calibration lamps (discharge lamps, CL) when mirror M3 is switched into the right position. Putting mirrors M1 or M2 at 45° with respect to the laser beams, the pump or Stokes beam, respectively, can be directed to the monochromator for exact determination of the laser wavelengths.

The CARS signal is detected by a Model RCA C31024A fast photomultiplier (PM). The intensities of pump and Stokes laser are measured by photodiodes (D1 and D2, respectively). The output signals of PM, D1 and D2 serve as input signals for the computer system. By means of the D1 output the pump laser triggers the complete electronic system for each laser shot. The computer controls the stepping motor of the double monochromator, the wavelength of the Stokes laser, position of mirrors M1–M5 and the shutter. Instead of a solid sample mounted in a cryocooler, as shown in Figure 23, a cell for liquids can also be used at the same place, which then allows CARS spectra of liquids to be obtained. The apparatus can be easily modified for CARS difference spectroscopy, which allows the simultaneous measurement of CARS spectra of two different samples under identical conditions. CARS difference spectroscopy can be used similarly as Raman difference spectroscopy for accurate determination of small frequency shifts and bandwidth changes in liquid mixtures, particularly when the sample is fluorescent.
Experimental problems may arise for CARS spectroscopy on samples with strong and broad absorption in the spectral region of interest. In such cases, the usual measurement procedure in which the CARS spectra are taken in transmission may be limited or even impossible. To overcome these difficulties, a backscattering CARS technique has been developed by Weippert et al.\textsuperscript{(112)} The backward CARS signal is normally negligibly small compared with the forward signal because of a large phase mismatch.\textsuperscript{(113)} However, in the case of strongly absorbing samples the short interaction length \( L \) (see Equation 51), which is then in the submicrometer range, causes the phase-matching condition to become less significant. Then, the backscattering CARS signal of strongly absorbing samples can have intensities even higher than those obtained in the conventional way, i.e. in a forward directed beam arrangement.

In order to observe backward scattered CARS signals from the surface of an opaque sample a special CARS set-up has been made, which is essentially the standard configuration as displayed in Figure 23 with specific modifications. The latter is shown in detail in Figure 24. Here, the sample area from Figure 23 is reproduced together with the modification. In this case, the Stokes beam runs parallel above the pump beam. Both are focused by the achromatic lens (AL1) and then deflected downwards by the mirror M6. The common focus is on the surface of the sample. The reflected upcoming beams including the generated CARS beam are reflected by mirror M7 so that after lens AL2 they again travel horizontally. This arrangement permits the CARS study of the surface of a highly absorbing sample which could be either a solid or a liquid.

Most of the CARS studies performed until now have been on gaseous samples. The main reason for this is the exceptionally high resolution combined with reasonable signal strengths. Although the nonlinear susceptibility \( \chi^{(3)} \) of a gas is about two orders of magnitude smaller than that of a typical liquid, the interaction length can be much larger. There is nearly no dispersion of the medium if excitation is away from absorption and, hence, the phase-matching condition (Equation 46) requires a collinear beam arrangement. Since the optical breakdown threshold for gases is orders of magnitude higher than for liquids or solids, the high output power produced by the second harmonic of a Nd: YAG laser (\( \omega_L = 532 \text{ nm} \)) and a dye laser (angular frequency \( \omega_S \)) pumped simultaneously by \( \omega_L \) can be profitably used. Thus the CARS signal produced in gases with such a relatively simple CARS apparatus can be nearly as large as in liquids.\textsuperscript{(103)} The high intensity beams with angular frequencies \( \omega_L \) and \( \omega_S \) can be best separated from the incident beams using a prism, dichroic mirrors or interference filters rather than a monochromator as shown in Figure 23.

### 5.2.2 Multiplex Coherent Anti-Stokes–Raman Scattering

Scanning CARS measurements require quite long recording times which may be too long with respect to the evolution of physical phenomena to be studied (e.g. chemical reactions). For such cases multiplex CARS is an attractive alternative to the single-frequency pulsed techniques. In multiplex CARS, the Stokes beam at \( \omega_S \) is produced by a broad band laser (typically 150–200 cm\(^{-1} \)) and the full spectrum (150–200 cm\(^{-1} \)) at anti-Stokes angular frequency \( \omega_{AS} \) is recorded in a single laser shot.\textsuperscript{(114)} A spectrograph with an optical multichannel analyzer (preferentially a cooled CCD camera) is needed for this purpose. In this case, however, the resolution is limited by the spectrograph and/or the optical multichannel analyzer employed. It should be noted that the multiplex CARS signal obtained from a single laser shot is comparatively small. However, averaging over many shots gives CARS spectra of similar quality as scanning CARS spectra if the lasers have comparable output power.

### 5.2.3 Femtosecond Time-resolved Coherent Anti-Stokes–Raman Scattering

Time-resolved CARS has produced much important information on the dynamics of molecular vibrations and rotations.\textsuperscript{(115–118)} In particular, vibrational dephasing time constants in liquids and solids could be determined with this technique.\textsuperscript{(119–122)} In these experiments...
pump and tunable Stokes beams serve to produce a coherent polarization oscillation in a medium at a resonant vibrational frequency. A separate time-delayed probe beam then generates an anti-Stokes signal whose intensity decreases with time due to dephasing and population-changing collisions. For solids and liquids, dephasing times are only a few picoseconds but in low density gases the signals persist for much longer periods.\(^{115}\)

Recent technical developments in ultrashort-pulse lasers enable the CARS spectrosocist to obtain coherent light pulses shorter than 100 fs. This time scale corresponds to the period of molecular vibrational motions \((100 \text{ fs} \approx 100 \text{--} 150 \text{ cm}^{-1})\) depending on the shape of the pulse, for example). One is therefore able to coherently excite many vibrational modes at a time and monitor relaxation processes in real time.

Femtosecond time-resolved CARS experiments were first reported by Leonhardt et al.\(^57\) Following studies\(^{123,124}\) showed beating patterns and fast decays of the coherent signal for several molecular liquids. Okamoto and Yoshihara\(^{125}\) reported the observation of femtosecond time-resolved CARS under various polarization conditions. They also observed time-resolved CARS under prereesonance and rigorous resonance conditions, which gave useful information on the vibrational relaxation in electronically excited states. With their femtosecond time-resolved CARS apparatus, the schematic diagram of which is displayed in Figure 25, they were able to study the femtosecond vibrational dephasing of a variety of molecular vibrations,\(^{126\text{--}130}\) among them the \(\text{C} = \text{N}\) and \(\text{C} = \text{C}\) stretching vibration in liquid nitriles and liquid alkynes, respectively.

The basis of the experimental femtosecond CARS apparatus developed by Okamoto and Yoshihara\(^{125}\) which is reproduced in Figure 25 is essentially the same as that of Leonhardt et al.\(^57\) and Zinth and Kaiser\(^{123}\) with the addition of the possibility to change the polarization of the laser radiation. The main parts of the system are two dye lasers with short pulses and high repetition rates, pumped by a CW mode-locked Nd:YAG laser (1064 nm, repetition rate 81 MHz). The beam of the first dye-laser which produces light pulses with 75–100 fs duration is divided into two parts of equal intensities and used as the pump and probe beam. After fixed (for the pump beam) and variable (for the probe beam) optical delay lines, the radiation is focused onto the sample together with the Stokes radiation produced by the second laser (DL2), which is a standard synchronously pumped dye laser. The anti-Stokes signal generated in the sample is separated from the three input laser beams by an aperture, an interference filter, and a monochromator, and detected by a photomultiplier. For further details we refer to Okamoto and Yoshihara.\(^{125}\)

![Figure 25 Schematic diagram of a femtosecond time-resolved CARS apparatus. \(\omega\)
Although time-resolved CARS is a powerful spectroscopic tool to study the vibrational relaxation of molecular systems, the information on dephasing dynamics via scattering from the isotropic part of the Raman tensor is often obscured by additional contribution of relaxation effects and the nonresonant part of the third order nonlinear susceptibility. An elegant femtosecond three color polarization allows to suppress the unwanted contributions by several orders of magnitude. Recently, femtosecond time-resolved CARS was applied in order to investigate simultaneously the dynamics of the electronic ground and excited state. As model system iodine vapor has been chosen. The experimental setup is shown in Figure 26. The output of a 76 MHz mode-locked Ti:sapphire laser (Coherent MIRA) was passed into a Nd:YAG-pumped regenerative Ti:sapphire amplifier (Clark-MXR) operating at 1 kHz. The pulses were stretched to a duration of \( \leq 200 \) ps before amplification. The output pulses were recompressed yielding less than 100 fs with an energy of \( \approx 1.5 \) mJ at 800 nm. In order to have two different colors available, the 800 nm pulse train was split into two parts by means of a 1:1 beam splitter. Using two four-pass optical parametric generators (OPGs) from Light Conversion, two independent wavelengths could be chosen. The laser pulses were produced using sum frequency generation between signal and idler output of the OPG as well as second harmonic generation of either the signal or the idler light. The pulses were finally compressed in double-pass two-prism arrangements resulting in temporal pulse widths of about 70 fs.

One of the OPG outputs was branched by a 1:1 beam splitter to produce the two pulses \( \omega_{pu} \) and \( \omega_{pu} \) (see for notation Figure 18). The two pump beams were then aligned parallel to one another and spatially overlapped at the common focus in the cell by the achromatic lens L1. The Stokes beam \( S \) (output of the second OPG) was aligned parallel to and spatially separated from the two pump pulses and passed through the top of lens L1, focusing in the same region as the two pump beams. This folded BOXCARS configuration (see also panel (b) of Figure 18) was employed in order to separate the signal from the incoming pump and probe pulses. In this geometry the phase-matching condition is fulfilled.

The pump pulses and the probe pulse could be delayed to each other by means of Michelson interferometer arrangements. The pump pulse \( \omega_{pu} \) and the Stokes pulse \( S \) were kept temporally overlapped and fixed. The CARS
transients were recorded as a function of delay time $\pm \Delta t$ between the pump pulse $p_1$ and the two fixed and time coincident pulses $p_2$ and $S$ (see panel (c) of Figure 18). The relative timing between the different pulses was varied with a computer-controlled actuator that allowed for optical delay up to 3 ns with a minimal stepsize of 6 fs. The determination of the position of temporal overlap (time zero) between the different beam pairs was made using a cross-correlation apparatus with second harmonic generation as well as sum frequency mixing in a thin phase-matched BBO crystal.

The femtosecond CARS signal pulse as generated in the sample cell travels in a direction determined by the phase-matching condition. This direction is different from that of the incident laser beams (see panel (b) of Figure 18), and the signal could thus be easily separated by a spatial filter. The CARS signal beam was collimated by a second achromatic lens ($L_2$). After filtering the straylight by means of a monochromator (Acton SpectraPro-500), the anti-Stokes signal was detected by a fast photomultiplier tube (RCA C31024 A). The signal-to-noise ratio was enhanced by use of a boxcar integrator (EG&G model 4121B) in gated-integrator mode, as well as by numerical averaging of several pulses.

With this setup the vibrational/rotational dynamics of the iodine molecule in its excited electronic B-state as well as in its ground electronic X-state could be simultaneously studied in one experiment.$^{58,137}$

### 5.2.4 High-resolution Continuous Wave Coherent Anti-Stokes–Raman Scattering

One of the main advantages of CARS and also of other nonlinear Raman spectroscopies is the high spectral resolution that can be achieved in spectra of gases at low pressures. The reason for this is that the instrumental resolving power in these techniques depends only on the convoluted linewidths of the lasers used for excitation, whereas in linear Raman spectroscopy the resolution is mainly determined by the monochromators used to disperse the observed scattered Raman light.

High resolution ($\approx 10^{-3}$ cm$^{-1}$) CARS spectra can be achieved with single-mode CW lasers. The obvious disadvantage, however, is the drastically reduced CARS signal level due to the low power levels of CW lasers. The first CW CARS experiment was reported by Barrett and Begley,$^{138}$ followed by experiments performed by Henesian et al.$^{139}$ and Fabelinsky et al.$^{140}$ More recently Schröttet al.$^{141}$ Schröttet and Boquillon,$^{142}$ and Frunder et al.$^{143}$ have developed a very efficient CW CARS spectrometer with a resolution of 0.001 cm$^{-1}$ (30 MHz). The high efficiency was achieved by intracavity...
excitation in an argon ion ring laser modified from a commercial laser head. In this way an intracavity power of 100 to 200 W in a single longitudinal mode at 514.5 nm, selected by an intracavity etalon, was obtained. Figure 27 shows the schematic arrangement of the argon ion ring laser in the CARS spectrometer including the provisions for an active stabilization to a hyperfine component in the absorption spectrum of iodine. The second, tunable laser frequency is provided by a commercial dye ring laser pumped by a second argon ion laser. The beam of the dye ring laser is coupled into the cavity of the argon ion laser at the prism and is focused collinearly with the argon ion laser beam inside a specially constructed gas cell for intracavity CARS excitation. The generated CARS beam is transmitted by the dichroic end mirror of the argon ion laser and spectrally purified by a prism and a grating monochromator. With this sophisticated set-up high resolution CARS spectra can be generated in the spectral region from about 2000 to 3500 cm\(^{-1}\). Several applications to molecules in the gas phase have been reported.

### 5.3 Stimulated Raman Gain Spectroscopy and Inverse Raman Spectroscopy

As outlined in section 3.3, both SRGS and IRS or SRLS fall into the class of coherent nonlinear Raman techniques. SRGS and IRS differ only in that spectra are obtained in the former case by using a Stokes shifted probe laser to scan the gain profile produced by a pump laser source, whereas in the latter case of IRS, an anti-Stokes shifted probe laser is used to scan the absorption profile (loss) on the opposite side of the spectrum relative to the pump frequency. Thus, scanning of the frequency of one of the laser sources relative to the other results in a direct display of the Raman spectrum. The only difference in respect to the spontaneous Raman spectrum will be that, since this is a stimulated process, the signal will scale as the difference in population between the upper and lower level rather than being directly proportional to the lower-level population. The advantages of SRGS and IRS are that the signal (in contrast to CARS) is linearly proportional to the spontaneous Raman scattering cross-section (and to the product of the two laser intensities), and that the phase-matching condition is automatically fulfilled and there is no nonresonant background. The resolution of the nonlinear Raman techniques is limited only by the laser linewidths. These qualities give the stimulated Raman techniques particular appeal under conditions where interference from background luminescence is problematic or in situations where very high resolution is required. The main disadvantage of these techniques, however, is that they are quite sensitive to laser noise. The latter requires high stability in laser power. Pioneering work on stimulated Raman spectroscopies was performed using pulsed high-power laser sources in order to induce appreciable Raman gain or loss that could be easily observed. Later techniques employed stable CW lasers and detect the small \(\approx 10^{-5}\) changes in intensity due to Raman gain or loss. Due to complexity, only a few stimulated Raman gain and loss spectrometers with main application in high resolution molecular spectroscopy have been built since the fundamental developments by Owyoung et al. in 1978. An important improvement has been the realization of the quasi-CW stimulated spectrometer, wherein a single-mode stable CW laser provides a low-noise probe source and a high-power respectively pulsed laser system provides the pump source. Such a scheme is diagrammatically shown in Figure 28 for inverse Raman (Raman loss) spectroscopy. Here, the anti-Stokes shifted probe laser (angular frequency in this case is \(w_S\)) is temporally gated on for a time (100 \(\mu\)s) that is long compared to the high power pump pulse (angular frequency \(w_P, 6\) ns), yet short enough to result in a low duty cycle, and thus preclude premature saturation of the detector. As the two beams cross in the sample at their common focus, the Stokes gain or anti-Stokes absorption produced by the pump beam is reflected in an amplitude modulation of the probe beam. Elimination of the background probe level is achieved by high-pass filtering. Such an approach thus incorporates both the large gains in sensitivity using a high-power pump source and the stable noise free advantage of a CW probe laser. Also, since the pump source is repetitively pulsed, a boxcar averager may be used to provide signal averaging which increases the signal-to-noise ratio even further. Similar to pure CW systems, the spectrum is obtained by scanning either the pump or the probe laser, which allows the gain or absorption profile to be displayed directly.

The construction of a spectrometer for high resolution stimulated Raman spectroscopy based on the quasi-CW approach described above, has been reported recently by

---

Figure 28: Schematic diagram for quasi-CW IRS. (Reproduced from Owyoung et al.)
Bermejo et al. Their experimental set-up is shown in Figure 29. It is also suitable for performing high resolution IR absorption spectroscopy. A frequency stabilized single mode argon ion laser delivers the probe beam. The tunable pump beam is produced by means of an argon ion pumped stabilized dye ring laser, whose output is amplified by a three stage dye amplifier which is pumped by a pulsed, frequency doubled Nd:YAG laser. A Fabry–Perot interferometer and a wavemeter serve for the accurate wavelength determination of the dye laser output. Part of the power of the pump and probe laser beams is used for generating a tunable, narrow-band difference frequency by means of non-linear mixing in a LiNbO3 crystal. Hence, simultaneous recording at high resolution IRS and IR difference frequency spectra is possible with this instrumentation. Both resolution and absolute accuracy of the observed Raman transitions are of the order of 10⁻³ cm⁻¹.

5.4 Photoacoustic Raman Spectroscopy

Acoustic detection of the Raman process using CW laser sources was first performed by Barrett and Berry. In PARS the energy is deposited in the sample by the stimulated Raman process and the PARS signal is detected by sensitive acoustic methods. The use of high-power pulsed laser sources again gave great improvements in the sensitivity of this technique. This method is limited by the requirement of a static (“quiet”) sample and by the pressure necessary to transfer the acoustic signal to the microphone. The advantage of the method, which originates from the non-optical nature of the detection, is the absence of a Rayleigh line, because no energy can be deposited into the sample at zero Raman frequency (\(w_R\)), which enables to record pure rotational Raman spectra without any interference caused by Rayleigh scattering.

Since the pioneering work by Barrett and coworkers only a few PARS experiments have been applied to some molecular gases. The high potentiality of this technique when combined with the advantage of high-resolution spectroscopy using narrow linewidth lasers has been demonstrated recently by Rotger et al. By a simple modification of their inverse Raman spectrometer, they were able to perform high resolution (0.005 cm⁻¹) PARS and CARS spectroscopy of gases at about 10 torr ≈ 1.3 kPa. Their system, which is essentially a CARS set-up where a condenser microphone is inserted in the sample cell just in front of the beam focal point, is shown in Figure 30. Pump (\(w_L\)) and Stokes (\(w_S\)) lasers are a frequency doubled single mode Nd:YAG laser and a pulsed amplified tunable dye laser, respectively.

5.5 Ionization-detected Stimulated Raman Spectroscopy

IDSRS combines high resolution stimulated Raman spectroscopy with highly sensitive resonance enhanced multi-photon ionization (REMPI) to achieve an increase in sensitivity of over three orders of magnitude. The experimental apparatus to perform IDSRS is shown, in
The sensitivity of the technique is primarily limited by the level of background ionization present even when the Raman pump sources are off resonance. By using a segmented electrode design in conjunction with a differential amplifier (see Figure 31), it is possible to differentially detect the IDSRS signal relative to the background signal arising from regions where the three input laser beams do not cross. The background signal can thus be suppressed, significantly increasing the overall signal-to-noise ratio. High spectral resolution in the first step of the process is achieved by using two near-Fourier-transform limited bandwidth (0.002 cm\(^{-1}\)) pulsed sources to drive the stimulated Raman transition. The latter two light sources originate from a single-mode CW krypton ion laser (647 nm) and a tunable single-mode CW dye laser (in Figure 31, 586 nm), respectively. Both of these sources are pulse amplified up to \(\approx 1\) MW in

---

(Reproduced from Hartland et al.\(^{159}\))
Nd:YAG-pumped, dye-amplifier chains. Since the resolution of the Raman spectrum is dependent only on the VIS Raman excitation sources, the linewidth requirements on the UV ionization laser are much less stringent. The frequency doubled output of a commercial Nd:YAG pumped dye laser is therefore sufficient for this source.

High-resolution Raman spectra are obtained by scanning the frequency of one of the Raman excitation sources and monitoring the ionization signal as a function of the frequency difference between this laser and the second, fixed frequency, pump laser. The IDSRS technique has also been applied for N\textsubscript{2} \textsuperscript{157}.

Since IDSRS involves the detection of ions, it can be readily implemented with mass-selective detection of those ions \textsuperscript{158–160}. In fact, ion-mass analysis (by time-of-flight techniques, for example) greatly enhances the capabilities of the IDSRS techniques.

Besides the frequency domain versions of mass-selective IDSRS, in which the frequency is scanned while photo-ions are detected, the same group has also developed Fourier transform versions of this scheme (FT-IDSRS) \textsuperscript{159}. In this method the two stimulating Raman excitation beams are directed through a Michelson interferometer before being combined with the ionization UV laser field (see Figure 32). Photoions are then detected as a function of interferometer delay. The result is an interferogram that upon Fourier transformation yields a Raman spectrum whose resolution does not depend on the bandwidths of the Raman excitation sources, but, instead, on the delay range of the interferometer scanned in the experiment. Mass-selective IDSRS and FT-IDSRS have been used in a number of studies, including one of the benzene dimer \textsuperscript{160}.

ACKNOWLEDGMENTS

The authors wish to thank V. Roman and S. Schlücker for their help in preparing this paper. 8 The Mass of the Sample
9 Conclusions

This is a very short article to introduce the subject of thermal analysis and to indicate how the following reviews fall into the general scheme of things. These more detailed reviews on the various topics should be read carefully, as they do cover the subject in depth. In each review a list of references is provided, which should allow the more serious reader to follow the development of each subject by reference to original research articles.

1 THERMAL ANALYSIS

This term covers the use of a variety of techniques to follow the change in any property of a system or sample as the system is subjected to a programmed range of temperatures. The use of such techniques is to be found in many industries. The program of temperature change is generally one of changing the temperature linearly with time. This is the program selected by most of the industrial users as it saves time and hence money to get information in this way. It must be emphasized that the measurement of the property is recorded at the particular temperature indicated and not the property of the system that has been bought back to ambient temperature.

In the reviews that follow, two main thermal analysis techniques are described, namely Thermogravimetry and Differential Scanning Calorimetry and Differential Thermal Analysis. These need to be defined in order to appreciate the instrument and the experimentation. Thermogravimetry (TG) is possibly the most widely used technique in thermal analysis. It involves the measurement of the mass of a substance as a function of temperature while the substance is subjected to a controlled temperature program. The other technique noted above is calorimetry but goes by two different names, which at first glance is rather confusing. Differential thermal analysis (DTA) is a technique in which the temperature difference between a substance and a reference material is measured as a function of temperature while the system is subjected to a controlled temperature program. Differential scanning calorimetry (DSC) is a technique in which the difference in heat flow to a sample and to a reference is monitored against temperature while the entire system is subjected to a controlled temperature program. Put boldly, if the system operates qualitatively, merely indicating an endothermic or exothermic event, then it will be termed DTA by the instrument manufacturers. If on the other hand the instrument performs as a calorimeter and indicates the enthalpy change for an event, then it termed a differential scanning calorimeter. It is often advantageous to combine two or more of these thermal analysis techniques so that two probing units, e.g. measurement of mass (TG) and changes in heat capacity of the system (DTA or DSC), operate on the same sample. Such a combination goes under the name of Simultaneous Techniques in Thermal Analysis.

Gas analysis performed when the sample under investigation is subjected to a rising temperature program is seldom used as a single technique but is more often used in conjunction with another thermal analysis technique in a simultaneous fashion. The techniques of thermal analysis are to be found in the literature applied in all fields of science. As an example, the application of such techniques to inorganic chemistry is outlined here as one of the subjects reviewed (see Inorganic Systems, Thermal Analysis Applications to).

2 TERMINOLOGY

It has been found necessary to use a common terminology and methods of reporting data obtained on thermal analysis instruments. The International Confederation for Thermal Analysis and Calorimetry (ICTAC) has produced publications and recommendations, on the nomenclature to be used, on calibration methods, and the symbols used to represent the techniques utilized. The symbols and definitions used above are the recommended ICTAC definitions currently in practice at the time of writing. However, the definitions and the abbreviations are constantly under review. New techniques or modifications of older techniques require that this process of a common technology be re-examined.
3 THE ADVENT OF THE COMPUTER

The computer forms an essential part of any thermal analysis unit. It can be used for instructional purposes. It is also used to control the equipment, i.e. to program the temperature regime, and to record the properties that are being measured. It is used to collect this data for storage, and retrieval as the occasion demands. The computer can be “loaded” with programs that allow for an interpretation of the events recorded. Basic data collected from thermal analysis experiments can now be processed in a very short time. These computations would previously have taken up much valuable time as they would have involved manual calculations. Finally, the computer can be used to simulate the behavior of the instrument during a virtual experiment. Thus by inserting the values of the pre-exponential term, the activation energy, and the type of kinetic equation, into the computer, a theoretical simulation of thermal analysis experiments can be achieved. It is also possible to run an electronic library of past thermal analysis experiments for comparison purposes.

4 PROCEDURAL VARIABLES IN THERMAL ANALYSIS

It must be recognized that there are procedural variables that might affect the results of any thermal analysis experiment. Thus a large chunk of wood is logically expected to behave differently to sawdust although the two are probably chemically related. A rock of limestone would give a different result from a ground sample of the same material.

The sample under investigation must be adequately described. The sample is generally a solid and it must be remembered that, alone among the phases, the solid phase to be adequately described requires a detailed record of its past history. Also important are the purity of the sample and its chemical composition, and if possible there should be an attempt at giving its formula. In some instances the sample may be present in a diluted form.

5 THE SAMPLE HOLDER

The geometry and the material used in the construction of the sample holder are important. The sample holder should not interact with the sample during the heating regime. The different thermal conductivity values of the materials used in the sample holder can cause alterations in the heat transfer, which can be apparent in the final thermal analysis plot. The geometric shape of the holder can cause a reaction to change from, for example, a predominantly diffusion mechanism in a narrow holder, to a reaction interface process in a shallow holder.

6 THE RATE OF HEATING

The rate of heating can vary from an isothermal experiment to a heating rate in which several hundred degrees are scanned in a very short time. The response of the sample to such changes can be drastic, and experience and theory have made investigators aware of this fact. This comment also applies to those thermal analysis experiments where the sample is cooled. Very fast cooling, called quenching, can cause a higher temperature state to be preserved at the lower temperature. Very slow heating, called annealing, is most likely going to allow the higher temperature form to transform to a state stable at the lower temperature. There is also the possibility that the design of the equipment might result in thermal lag between different components of the unit and this could be affected by the rate of heating.

7 THE ATMOSPHERE SURROUNDING THE SAMPLE

In thermal analysis experiments the gaseous environment around the sample is going to influence the results. This follows from a casual glance at any textbook on thermodynamics, and the experimenter in thermal analysis should be aware of such a fact. Carrying out the thermal analysis experiment is possible at pressures ranging from a very high vacuum to several hundred times atmospheric pressure. Not all experiments are performed over such an enormous range, but any transformation studied in thermal analysis experiments would be affected by changes in the pressure of the gaseous environment. In fact most experiments on commercial units are studied at atmospheric pressure. These comments apply to both physical transformations and chemical changes. At atmospheric pressure (which is the region where most experiments are run), the nature of the environmental gas and the rate at which the gas is passed over the sample are important. Such features as the thermal conductivity of the gas may affect the temperature range over which the transformation may be noted. If the partial pressure of the product gas over the sample is altered during the thermal analysis experiment, then the temperature range of the transformation may be altered in conformity with Le Chatelier’s Principle. The decomposition of calcium carbonate is a case that may be cited. Increasing the partial
pressure of carbon dioxide around the sample will push the decomposition range into higher temperature regions.

8 THE MASS OF THE SAMPLE

The mass of the sample in thermal analysis experiments, and the manner of its distribution, may affect the result. The sample may be present as a fine powder or as a compressed mass (as in a pharmaceutical tablet). This may be summed up, by simply stating that the manner in which the sample is packed is an important factor. It is also a wise precaution to sieve the sample and to investigate the decomposition of the sieved ranges. Again the decomposition of calcium carbonate serves as an example. The small particle size fractions possess a larger surface area than the larger particle size fractions. Hence, the kinetics of the sample can be affected by the initial surface area of the material, and the smaller size fractions will possess a greater chemical reactivity and will decompose in a lower temperature range.

9 CONCLUSIONS

It must be emphasized that the points made above may be substantiated by logical and theoretical reasoning. However, this is no substitute for carrying out actual experiments, as some systems may be more complex than is at first apparent. In such instances some careful experimentation is probably worth more than a simple exercise of theory. Theory has to be based on experiments and not the other way around. The literature on thermal analysis is constantly expanding. Chemical Abstracts run a CA Selects on thermal analysis. There are several textbooks on the subject, but many of those quoted in review texts of this kind are out of date and not so easily found. It is best to consult the nearest library in order to make an up-to-date choice. Analytical Chemistry runs a two-yearly review of the subject, which may prove to be helpful.

3.15 Polymer Fabrics Identified by Differential Scanning Calorimetry
The importance of thermal analysis methods in thermal and material science has proved awesome. Differential thermal analysis (DTA) and differential scanning calorimetry (DSC) have had a great impact on material science by enabling the measurement of a great number of physical and chemical properties. These techniques have allowed elucidation of endothermic and exothermic processes at temperatures ranging from very low (−120°C) to high (DSC 600°C and DTA 1800°C). Some of the physical properties measured by these thermal analytical methods include melting transitions, crystallization temperatures, enthalpy of fusion and crystallization, specific heat capacity, liquid crystal transitions, vaporization, sublimation, solid–solid transitions, thermal conductivity and the glass transition temperature. Chemical properties monitored by DSC and DTA are dehydration, decomposition, oxidative reactions, solid state reactions, chemisorption, combustion, polymerization, curing and catalyzed reactions.

In DTA, the temperature difference between the substance and a reference material is measured as a function of temperature, while the substance and reference material are subjected to a controlled temperature program. In DSC, the difference in energy input into a substance and a reference material is measured as a function of temperature, while the substance and reference material are subjected to a controlled temperature program. Two modes, power compensation DSC and heat flux DSC, can be distinguished, depending on which method of measurement is used.
are located external to the sample. Boersma\(^{(27)}\) states that this experimental condition, external sensors, must be met in order to make calorimetric measurements. Semiquantitative calorimetric measurements have been accomplished when the DTA conditions operate in both modes, first when the sensor is in contact with the sample, and then when the sensor is removed from the sample. The TA Instruments (TAI) high temperature DTA is capable of either mode.\(^{(25)}\) Without sample couple liners present, the instrument performs as a classical nonquantitative DTA. With liners, however, accuracy and precision of calorimetric measurements of 5% can be observed. DSC typically provides calorimetric accuracy and precision to better than 1%. It is desirable to have constant calorimetric sensitivity, but it is not a necessary condition for a DSC instrument. Differential scanning calorimeters with constant calorimetric sensitivity where the calibration constant is not a function of temperature have an output directly in heat flow units of milliwatts.

Differential scanning calorimeters operate by one of two methods, differential temperature and temperature servo measurements. An example of the differential temperature instrument is the TAI DSC 910 system. Figure 1 is a cross-sectional view of this DSC cell. The cell uses a constantan disk as its primary means of heat transfer to the sample and reference positions, as one element of the temperature measuring thermoelectric junctions. The experimental sample and reference are placed in containers or pans that rest on raised platforms on the constantan disk. Heat is transferred through the disk and into the sample and reference via the containers. The differential heat flow to the samples and reference is monitored by chromel–constantan area thermocouples formed by the junction of the constantan disk and a chromel disk that covers the underside of each platform. The differential temperature, \(T\), from the sample and reference thermocouples, is fed to a variable high-gain amplifier where the signal is amplified, electronically scaled to read directly in heat flow units and finally displayed on the y-axis. Chromel and alumel wires are connected to the underside of the chromel disk and the resultant chromel–alumel thermocouple is used to monitor the sample temperature directly.

When a sample is programmed at a constant heating rate through its melt, the heat capacity of the sample increases in theory to infinity and the sample temperature becomes invariant. Therefore, a temperature is developed between the sample and reference temperature which is constantly rising. This temperature signal is proportional to the heat flowing into the sample endothermically as part of the transition. When the amplified and scaled signal presented to the computer in milliwatts is integrated over time, a value for the heat in millijoules associated with the transition is obtained.\(^{(24)}\)

The second type of instrument, the temperature servo system, is shown in Figures 2 and 3.\(^{(25)}\) In this design, the sample and reference pans are placed in close contact with platinum resistance thermocouples (PRTs) which are used to measure their temperature at any given moment. In addition, the unit has two individual heaters that control the heat flow to these samples.

When the sample is temperature programmed through its melt, the sample temperature becomes essentially invariant, and the difference temperature signal, \(\Delta T\), developed between it and the reference is amplified, scaled and displayed as the output from the device, see Figure 3.\(^{(25,28)}\) The process continues when the differential

---

**Figure 1** Cross-sectional view of a DSC cell.

**Figure 2** Schematic diagram of power compensated DSC cell.
Figure 3 Schematic diagram of temperature servo system.

power is supplied back to the sample heater attempting to reduce the temperature difference between the sample and reference. The operating principle of a servo system requires the restoring signal, in this case a voltage signal to the differential heater, to be proportional to the offset, the temperature difference. If the temperature difference is zero, no differential power could be supplied by the servo system. An actual zero temperature difference can exist only if the servo amplifier gain is infinite; and it is not.

Calorimetry is the scientific field dealing with the measurement of the heat or energy content of various chemical and physical reactions. In a typical classical adiabatic calorimetric experiment, a chemical reaction may be carried out in a sealed container insulated from heat losses to the outside world. From the known heat capacity ($C_p$) of both the insulated container and its contents and the small measured change in temperature ($\Delta T$) of that system, the heat content of the chemical reaction, $H$, can be calculated, Equation (1):

\[
H = \Delta T \times C_p
\] (1)

The experiment is usually designed so that the change in system temperature remains small, usually several Kelvin. Under these conditions $C_p$ is constant. From these experiments we derive the definition of the calorie which is the unit of measurement for heat content or energy, or the amount of heat necessary to raise the temperature of 1 g of water at 15 °C, by 1 °C.

In DSC, the temperature profile of a sample seldom exceeds a few tenths of a degree. Therefore DSC instruments operate well under classical calorimetry conditions, from which thermodynamic data are almost exclusively obtained. (24)

Differential scanning calorimeters based on heat flux or power compensated measures the same quantity, the heat flow into (endothermic) or out of (exothermic) a sample.

1.2 Review of Modulated Temperature Differential Scanning Calorimetry

An innovation in DSC that has become a widely accepted technique is MTDSC. (29-38) It provides the same qualitative and quantitative information about physical and chemical changes as conventional DSC. MTDSC, however, provides unique thermochemical data that are not accessible with DSC. MTDSC overcomes the limitations of conventional DSC. The effects of baseline slope and curvature are reduced, thereby increasing the sensitivity of the system. Overlapping events such as molecular relaxation and glass transitions can be separated. Heat capacity can be more easily measured using this technique which requires a minimum number of experiments.

MTDSC uses the same conventional heat flux DSC cell system. Uniquely, it uses a different heating profile for the sample and reference as supplied by the furnace. Specifically, a sinusoidal modulation or oscillation is superimposed on the conventional linear heating ramp. Experimental procedures can vary from method to method for DSC, DTA, MTDSC and pressure differential scanning calorimetry (PDSC).

2 EXPERIMENTAL PROCEDURES

2.1 Optimization of Differential Scanning Calorimetry

Thermal Properties

The optimization of DSC is critical in acquiring accurate and precise data. Inspect the DSC cell and assure its good condition. For example, clean the thermal sensors by heating to 500 °C in air to burn off any decomposed materials. Use a brush to wipe off any debris that will interfere with the transfer of heat flow from the sample to the thermal sensor. Always use a purge gas. Typical inert gases are nitrogen and helium. Helium is used to enhance heat transfer. A nominal flow rate is set at 50 mL min⁻¹ for most instruments. Oxidative gases are oxygen or air at 21% oxygen and 79% nitrogen.

2.2 Calibration, Standards and Standard Methods

The instrument must be calibrated for temperature and heat flow on a regular basis. American Society for Testing and Materials, ASTM E697 (39) can be used to calibrate the DSC temperature (x-axis). ASTM E968 (40) is used to calibrate the heat flow (y-axis). The ASTM E1860 (41) protocol is used to establish elapsed time, which is especially important when considering International Standardization Organization (ISO) 9000 certification.

An excellent resource of known temperatures and heat of fusion for many standards is given in Table 1 (42) where

a The table summarizes the best known temperatures and heats of melting for many standard materials. These values may be used for temperature and/or cell constant calibration of the TA Instrument’s DSC or high temperature DTA.

b Sample sublimes.

c Sample oxidizes easily.

f Reacts with alumina.

g Amalgams with aluminum as low as 450°C, do not heat above 430°C.
h Shelf-life 1 week at room temperature.
i Amalgams with copper.

2.3 Sample Size

Thermal properties may be dependent on the specimen size and shape. A common sample size is from 1 to 10 mg. Replicates should be the same size to within 10%. Select the sample shape to ensure good contact.
with the pan or container. A uniform size and shape is desirable.

2.4 Sample Preparation and Pan Selection

Heating through transitions erases thermal history at lower temperatures. Mechanical treatment of the sample may produce localized heating or stress in the sample. Cryogenic grinding in a freezer mill creates easily handled powders. The low temperature sampling minimizes treatment effects. Cutting it from the bulk sample with a razor blade or clipper can attain minimum stress on the sample. Minimum temperature and time exposure of the sample is accomplished by the latter techniques. Films can be heat pressed and then paper punched out. However, the effects of heating and oxidation must be considered.

DSC pan or container selection is dependent upon specimen size and shape. One must also consider the maximum temperature of the experiment, if the pan is chemically inert and whether it retains vapors or not. Other factors to consider when selecting an appropriate pan for use is whether it has a high thermal conductivity, low heat capacity, and low cost.

DSC pan types include aluminum, copper, gold, platinum, glass, carbon, stainless steel and mild steel. The form of the pan can also be varied. It can be crimped, hermetically sealed, and contain a molecular leak with a laser drilled pin hole, an autosampler pan and a center raised solid fat index pan to fit over a thermal sensor.

An as-received pan must be cleared in order to remove oils or lubricants used in manufacturing the pan. Organic oils and lubricants can be removed with xylene, acetone, dried with nitrogen gas and stored according to ASTM E-1858-97.

One supplier of aluminum pans used calcium carbonate as lubricant. Excess calcium carbonate confounded oxidative studies where organic oils decomposed to yield acids. The relative oxidative stability varied considerably. Another vendor did not realize that when their supplier of aluminum pans stamped them out they were embedding small (less than 0.2 mm) particles of iron and copper. These metals are used to accelerate the oxidation of oils. These contaminants caused accelerated oxidation and a process that became out of control. The extraneous metals were only detected by scanning electron microscopy (SEM) with energy dispersive X-ray spectroscopy, see Figure 4. Table 2 gives an elemental analysis. When the peak area ratio of iron and copper to chromium was greater than two, the relative oxidation rate (inflection point-first derivative of the exothermic heat flow versus temperature curve) was out-of-control. This particular problem was eliminated by returning to a source of new containers with a high standard of quality control.

2.5 Differential Scanning Calorimetry Curve and Sample Analysis

A DSC or DTA baseline plot should be flat. The latter can be achieved through calibration with empty pans and application of the electronic correction. All samples have a baseline with an endothermic slope caused by the increasing specific heat capacity of the sample with increasing temperature, see Figure 5.
DSC baseline curvature cannot normally be corrected by calibration. However, if necessary, it can be eliminated by baseline subtraction, see Figure 6. Baseline slope and curvature can cause an error if integrating peaks over a broad temperature range and can make detection of a weak glass transition temperature, $T_g$, difficult, Figure 6(a) and (b).

Samples should be kept thin to minimize heat transfer problems. It is better to cut out a representative sample rather than crush it. Stresses could be imparted to the sample prior to thermal analysis. Typical sample mass in DSC is 10–15 mg for polymers. A goal is to achieve a change of 0.1–10-mW heat flow in going through a transition, see Figure 7. Use the lightest, flattest pan possible.

If the sample contains volatiles, put one or more pinholes in the lid of the pan before crimping in order to permit a continuous evaporation process.

2.6 Effect of Sample Specific Heat

Minimize differences in specific heat between the sample and the reference by adding aluminum to the reference pan. This improves the overall baseline; see Figures 8–10. Initiate a DSC analysis 2–8 min before the temperature of interest, depending on the heating rate, for example, 5°C min$^{-1}$ or 20°C min$^{-1}$. That is about 40°C before the temperature of interest ($2 \times 20°C \text{ min}^{-1} = 40°C$ and $8 \times 5°C \text{ min}^{-1} = 40°C$).
THERMAL ANALYSIS

2.7 Differential Scanning Calorimetry Sensitivity and Resolution

Adjust sample weight, heating rate and purge gas if necessary to improve sensitivity or resolution, see Table 3 and Equation (2)

$$\frac{dQ}{dT} = C_p \times \frac{dT}{dt} + f(T, t) \tag{2}$$

where heat flow = heat capacity × heating rate + kinetic component, and the kinetic component is a function of temperature and time.

2.8 Pressure Differential Scanning Calorimetry

A special pressure cell is needed for both high-pressure as well as low-pressure studies in nitrogen, air or oxygen. The sample of 1–3 mg, is weighed into an open pan as per the ASTM standard test method E-1858 for oxidation induction time (OIT). The OIT method, the sample, a drug, oil or polymer is heated to an isothermal temperature, 175°C at 35-MPa oxygen and 195°C at 14 kPa of air or oxygen. The extrapolated onset temperature is defined as the OIT. A second method, ASTM E-2009, oxidation onset temperature (OOT) is based on a DSC or PDSC. The OOT is defined as the extrapolated onset temperature in a plot of heat flow versus temperature. A thermogravimetric analyzer (TGA) coupled with a differential thermal analyzer, TGA/DTA, has also been used to determine the OOT of hydrocarbons in air. In this study, the sample size was 10 mg, the flow rate of air was 250 mL min⁻¹, heating rate was 10°C min⁻¹, and the sample pans were aluminum or platinum.

2.9 Differential Scanning Calorimetry Method and Thermoplastics

When analyzing thermoplastics with a standard DSC, the experimental program should include a heat–cool–heat cycle at 10°C min⁻¹. The first heat results are a function of material and an unknown thermal history. The cool cycle gives the sample a known thermal history. These results can be used to compare polymer crystallization properties. Finally, the second heat results are a function of material and a known thermal history. They will be useful for comparison of materials, for example polymers, see Figures 11–13.

2.10 Differential Scanning Calorimetry Method and Thermosets

When analyzing thermoset polymers by conventional DSC, the experimental program should include an annealing

period, then heat, quench cool and finally heat at a rate of 10–20 °C min⁻¹. Anneal at approximately 25 °C above the \( T_g \) onset to eliminate effects of enthalpic relaxation. The heat portion of the program is to measure the \( T_g \) and any residual cure (exothermic polymerization). Do not heat through the decomposition onset temperature; halt the experiment before decomposition occurs. Quench the sample, usually with liquid nitrogen or a dry ice–acetone slurry in a cooling can. This process will give the sample a known thermal history. During the final heating the \( T_g \) of the fully cured sample can be measured, see Figures 14–16.

Select an end temperature that does not cause decomposition of the sample in the calorimeter. Degradation products can condense in the cell and cause either corrosion of the cell or baseline problems. Use sealed glass ampoules or stainless steel pans that can take high pressure, >70 MPa, in order to study decomposition by DSC. The use of aluminum hermetically sealed pans can minimize corrosion and destruction of the cell liner. However, knowledge of the onset of degradation assists in lengthening the longevity of a DSC cell.

Figure 15 Thermoset: comparison of first and second heating runs.

Figure 16 Shift in \( T_g \) as a result of curing.

2.11 Differential Scanning Calorimetry Method and an Unknown

When examining an unknown sample, first test the sample by thermogravimetric analysis (TGA). Determine if the sample contains any volatiles and its decomposition temperature. If you do not have a TGA, weigh the sample before and after each DSC run. A 1% weight loss will often show up in the thermal curve as an endothermic peak unless the run is taking place in either air or oxygen where oxidation shows up as an exothermic peak.

2.12 Internal Melting Point Standard

Use an internal melting point standard; see Table 1, to verify transition temperature accuracy. Place the sample in a DSC pan. Invert the lid and crimp it in place or force it into the pan so that good contact is achieved on the top and bottom of the sample. Weigh the internal standard, for example, indium metal, into the inverted lid. Record the DSC thermal curve. The melting profile of indium will be superimposed on the curve, Figure 17.
2.13 Modulated Temperature and Conventional Differential Scanning Calorimetry

How does MTDSC differ from conventional DSC? DSC measures the difference in heat flow between a sample and an inert reference. MTDSC measures the same total heat flow. A DSC thermal curve records the data as a function of a linear change in temperature. A MTDSC thermal curve represents the change in temperature as a function of both a linear and a sinusoidal change. The linear change in temperature provides the same information, total heat flow, in both MTDSC and DSC. The sinusoidal change in temperature permits the measurement of heat capacity effects simultaneously with the kinetic effects.

The DSC heating rate can vary from isothermal to 20 °C min⁻¹. The MTDSC heating rate or ramp ranges from isothermal to 5 °C min⁻¹. The MTDSC temperature of modulation amplitude can range from 0.01 to 10 °C. The modulation period can vary from 10 to 100 s or 10–100 mHz in frequency.

In order to compare the two methods, MTDSC and DSC, poly(ethylene terephthalate) (PET) will be examined by the two methods. An MTDSC procedure is:

1. Equilibrate at 0 °C.
2. Modulate 1 °C every 40 s.
3. Maintain isothermal at 0 °C for 5 min.
4. Ramp at 5 °C min⁻¹ to 280 °C.

A corresponding DSC protocol is:

1. Equilibrate at 0 °C.
2. Maintain isothermal at 0 °C for 5 min.
3. Ramp at 20 °C min⁻¹ to 280 °C.

DSC records only the total heat flow in the sample. The modulated heat flow contains all thermal events occurring in the sample. Fourier transformation analysis of the modulated heat flow signal is used to calculate its average signal continuously. Total heat flow is the same in both techniques at the same average heating rate. The reversing heat flow is the heat capacity component of the MTDSC total heat flow. The nonreversing heat flow is the kinetic component of the heat flow, Figures 18–20.

2.14 Examples of Modulated Temperature Differential Scanning Calorimetry Characteristics

The MTDSC of an as-received molded blend of a PET/acylonitrilebutadiene terpolymer (ABS) is represented in Figure 21. The total heat flow thermal curve indicates a $T_g$ at about 60 °C and an exothermic event at about 97 °C. The total heat flow $T_g$ is the PET glass transition temperature. The exothermic event is the cold crystallization of PET. The cold crystallization event masked the ABS $T_g$. However, the reversing heat flow thermal curve clearly differentiates the ABS and PET $T_g$ values. The ABS $T_g(e)$, the
extrapolated onset \( T_g \), is 104.5 °C and the PET \( T_g(e) \) is 67.0 °C.

The \( T_g \) values and melt temperature of another polymer blend are clearly delineated in their first heat by MTDSC, see Figure 22. This blend contains PET, PC, and high-density polyethylene (HDPE). Overlapping thermal events confound the total heat flow curve. The exothermic PET cold crystallization overlaps the melting peak of HDPE. The reversing heat flow (W g\(^{-1}\)) thermal curve for reversible processes has a PET \( T_g \) at approximately 72 °C, a peak melt temperature for HDPE at 123 °C and a PC \( T_g \) at approximately 138 °C. The nonreversing heat flow, which is representative of nonreversible processes, shows an enthalpic relaxation endotherm at approximately 70 °C and the PET crystallization peak at ca. 115 °C.

2.15 Modulated Temperature Differential Scanning Calorimetry Experiments and the Glass Transition

Next, is a review of the MTDSC experimental factors that affect \( T_g \) properties of a thermoplastic and two elastomers. Also determined was the difference between glass transition temperature of elastomers by MTDSC and conventional DSC.

Aubuchon reported that “the frequency effect seen in MTDSC data is the effect that (occurs when) the heat

Figure 20 Quench cooled PET/MTDSC.

Figure 21 PET/ABS blend “as received” MTDSC.
capacity and reversing signals shift to higher temperatures with shorter periods (higher frequencies) of temperature modulation. The total heat flow signal does not show any frequency dependence. Both in dynamic mechanical analysis (DMA) and dielectric thermal analysis (DETA) the temperature shifts are accompanied by orders of magnitude change in frequency. The nonreversing heat flow signal is calculated from the difference of the total heat flow minus the reversing heat flow. Therefore, the nonreversing signal is also dependent on the frequency or period.

The MTDSC has two simultaneous ramps or heat rates. One is the average underlying heating rate (ramp) and the other, the instantaneous heating rate (amplitude). These ramp rates vary with the temperature modulation period and the amplitude. A shift in the extrapolated onset glass transition temperature, $T_g(e)$, of PS with frequency was observed. In the heating cycle, the $T_g(e)$ decreased by 1.3 °C with an increase of frequency from 25 to 100 s. In the cooling cycle, the $T_g(e)$ decreased by 3.4 °C with the same increase in frequency. The effect of the amplitude or instantaneous heating rate (0.1, 0.2, and 0.4 °C) on the $T_g$ at a constant heating rate of 1.5 °C/min showed a variation of 103.7, 103.9 °C (cooling cycle) and 104.4, 104.8 °C (heating cycle). Within experimental error, the $T_g$ did not vary with amplitude for PS. Aubuchon noted that a four-fold increase in frequency (10–40 mHz) or decrease in period (100–25 s) increased the $T_g$ by 3.0 °C. A four-fold increase in amplitude (instantaneous heating rate) increased the $T_g(e)$ by 0.3 °C.

There is a great interest in how the amplitude, heating rate or ramp and period affect the $T_g$ of polymers, for example, polybutadiene (PBD) and polystyrene-cobutadiene (SBR). A two to the third ($2^3$) factorial designed experiment examined PBD, SBR and a National Institute of Standards and Technology (NIST) high molecular weight PS. The following are the three MTDSC experimental variables and the low and high levels:

- Amplitude, 0.312 and 0.796 °C
- Period, 25 s (40 mHz) and 60 s (17 mHz)
- Ramp, 2.0 and 5.0 °C min$^{-1}$

Two sets of experimental variables are considered optimum for MTDSC:

1. amplitude, 0.312°C; period, 60 s (0.017 Hz); and ramp, 2.0 °C min$^{-1}$
2. amplitude, 0.796°C; period, 60 s (0.017 Hz); and ramp, 5.0 °C min$^{-1}$

The run order for this study was randomized. The following physical properties associated with the glass transition temperature were measured in the reversing mode of the MTDSC for the eight runs and the three polymers (see Figure 23):

- $T_g(e)$, the extrapolated onset glass transition temperature (°C)
- $T_g(i)$, the inflection temperature of the sigmoid-shaped $T_g$ curve (°C)
Figure 23 PBD: MTDSC amplitude variation.

- $\Delta C_p$ at $T_g$, the change in heat capacity at the $T_g$ (J g$^{-1}$ °C$^{-1}$) (y-axis change at $T_g$)
- $\Delta T$ at $T_g$, the change in temperature at the $T_g$, measured as the $T_g$ (end) minus the $T_g$ (e) (°C) (x-axis change at $T_g$), Figure 24.

Statistical and graphics analysis of the data was accomplished with JMP 3.2. A least squares fit model was used and the significance of the data was ranked by the t-test.

The most important MTDSC polymer property studied was the glass transition temperature, $T_g$ (e) or $T_g$ (i). Employing the t-test to evaluate the measured variations in the factorial design the absolute variation of the $T_g$ was $<2^\circ$C and this variation was not significant, Table 4. The interactive variables heating rate and period, heating rate and amplitude and period and amplitude also exhibited small variations in $T_g$ ($<2^\circ$C). The standard deviation of the $T_g$ (e) at the 95% confidence level was $\pm3^\circ$C for the polymers studied. The standard deviation of the $T_g$ (i) at the 95% confidence level was $\pm2^\circ$C. Wide variations in the MTDSC variables, heating rate, amplitude and period did not significantly affect the value of $T_g$.

However, variation of the period from 25 to 60 s did significantly affect the PS properties, the change in heat capacity at $T_g$ ($\Delta C_p$ at $T_g$) and the change in temperature at $T_g$ ($\Delta T$ at $T_g$). The $\Delta C_p$ at $T_g$ varied by 30% and the $\Delta T$ at $T_g$ by 25%. Variation of the period also caused similar changes in the $\Delta C_p$ at $T_g$ for SBR and PBD.

The t-test for all four glass transition properties of PS varied significantly with the changes in the period (inverse frequency). The properties of the elastomers studied were not affected by the variables, except for the period.

A comparison between the $T_g$ properties of PS as determined by MTDSC and conventional DSC is given in Tables 4 and 5 and Figure 24. The MTDSC values in the total heat flow mode were selected from the experimentally designed study and compared to an ASTM DSC test. The ASTM method calls for a heating rate of 10°C min$^{-1}$. The $T_g$ of PS at MTDSC heating rates of 2 and 5°C min$^{-1}$ were compared to standard DSC heating rates of 5, 10 and 20°C min$^{-1}$.

There was a small difference (0.7 and 1.0°C, respectively) between the $T_g$ (e) and $T_g$ (i) for PS when examined by MTDSC at 2.0 and 5.0°C min$^{-1}$. The $T_g$ (e) found by MTDSC and DSC both at 5.0°C min$^{-1}$ were 101.6°C and
104.0 °C, a difference of 2.4 °C. The standard DSC $T_g(e)$ increased with increasing heating rate, 5–20 °C min$^{-1}$, 104.0–107.1 °C. The optimum MTDSC conditions at 2 °C min$^{-1}$ yields a $T_g(e)$ at 101.1 °C and the ASTM standard DSC test at 10 °C min$^{-1}$ had a $T_g(e)$ of 105.2 °C. Therefore, when trying to compare $T_g(e)$ or $T_g(i)$ by MTDSC to the $T_g$ by standard DSC, a 3–4 °C difference should be expected.

The $\Delta C_p$ at $T_g$ and $\Delta T$ at $T_g$ values were higher for MTDSC than DSC. Based on total heat flow, PS had a $\Delta C_p$ at $T_g$ of 0.54 J g$^{-1}$ °C$^{-1}$ and $\Delta T$ at $T_g$ of 5.5 °C. In the MTDSC test the $\Delta T$ at $T_g$ for PBD and PS were <6 °C, while the copolymer SBR had a value of 12–15 °C. It appears that MTDSC can distinguish between copolymers and homopolymers. Examining a number of standard thermoplastics substantiated the observation that copolymers have a larger $\Delta T$ at $T_g$ than homopolymers.

The MTDSC variables do not significantly affect the measurement of the glass transition temperatures of the polymers studied. The period (frequency) did affect the $T_g$ properties of PS. Only the heat capacity change at $T_g$ was affected by the period variation for PBD and SBR. The MTDSC $T_g$ (reverse heat flow mode) value is more accurate than the standard DSC $T_g$ (total heat flow) measurement. There will be a 3–4 °C higher $T_g$ value when measured by standard DSC compared with the MTDSC value.

2.16 Power Compensated Differential Scanning Calorimetry Experimental Procedures

Next, is a brief review of the power compensated DSC experimental procedures. The optimum experimental conditions for dynamic differential scanning calorimetry (DDSC), DSC and DTA using a Perkin Elmer DSC is 1–75 mg, depending on the sensitivity required $^{70,71}$. The heating rate is 0.1–100 °C min$^{-1}$ depending on the application. A standard heating rate is 20 °C min$^{-1}$. The experimental conditions for a DDSC are 5–30 mg depending on the sensitivity required. 10 mg is a good default. The repeat pattern is 30 s heat up by 2 °C, 30 s cool down by 1 °C. A wide range of other values works too, but this is a good starting point and one that leads to specific heats within a few percent without any special calibration. A power compensated DSC is

described in Figure 25. A DDSC thermal profile is given in Figure 26.

2.17 Quantitative Differential Scanning Calorimetry and Differential Thermal Analysis

DSC and DTA are used to determine a wide range of physical properties of materials, including the glass transition temperature, melting temperature and solid–solid transition. To quantify these, transition temperatures instrument calibration is necessary with known standard materials. Therefore, calibration of DSC and DTA from −100 to 600°C consists of heating the calibration material at a controlled rate in a controlled atmosphere through a region of known thermal transition.\(^{(72,73)}\) The temperature and the heat flow difference in a heat flux DSC are continuously monitored, that is, between the calibration material and a reference material. A transition is marked by the absorption of energy by the specimen resulting in an endothermic peak in the heating mode of the thermal curve.

For a two-point temperature calibration, select a pure material in the temperature range of interest, see Table 1. The DSC or DTA can be calibrated with some degree of confidence with indium and zinc and the temperature correction factor can be extrapolated from about 50 to 500°C. However, in order to report transition temperatures in a journal article or in an internal communication, the temperature calibration is best when it is very close to the temperature that needs to be measured. As a minimum, two temperature standards that bracket the temperature of interest should be used.

\[
\begin{align*}
(a) & \quad \text{DTA} & & \Delta T_s - \Delta T_r = \Delta T \\
(b) & \quad \text{Quantitative DTA} & & \Delta T_s - \Delta T_r = \Delta T \\
(c) & \quad \text{Heat flux DSC or Boersma-type DTA} & & \Delta T_s - \Delta T_r = \Delta T \\
(d) & \quad \text{Heat flux DSC} & & \frac{dq}{dt} \\
(e) & \quad \text{Heat flux DSC} & & \frac{dq_s}{dt} - \frac{dq_r}{dt} = \frac{d(\Delta q)}{dt} \\
(f) & \quad \text{Power compensation DSC} & & \frac{dQ_s}{dt} - \frac{dQ_r}{dt} = \frac{d(\Delta Q)}{dt}
\end{align*}
\]

Figure 25 Comparison of DTA, power compensation DSC and heat flux DSC. S is the sample, R is the reference, T is the temperature and q is the heat.

\[\text{Figure 26} \quad \text{Measured curves of PET (}\beta_T = 5 \text{ K min}^{-1}, \quad T_a = 1 \text{ K, } \quad t_p = 30 \text{ s). (a) Measured with a heat flux DSC.} \quad \text{(b) Measured with a modified Perkin–Elmer DSC-7. Calculated from: 1, the underlying heat flow; 2, reversing component; 3, nonreversing component.} \]

2.18 Low-temperature Quantitative Analysis

Low-temperature calibration with mercury is valid. However, mercury is toxic and most researchers prefer to use the melting temperature of spectroscopic grade organic chemicals, for example, octane, −58°C, decane, −50°C or dodecane at −10°C.

DSC specimen containers are typically solvent cleaned aluminum or alumina pans. The pans can also be crimped with a lid or hermetically sealed to preserve the standard material. DTA specimen containers are typically thin walled glass capillaries with a flat bottom. Specimen containers must not react with a standard or sample material or melt in the temperature range of interest. Purge gases, like nitrogen or helium, are used at a flow rate of ca. 50 mL min\(^{-1}\). The mass of the standard is measured to the nearest 0.1 mg. The melting temperatures of calibration materials are given in Table 1. The most common melting temperature standards are indium at 156.6°C, tin at 231.9°C and zinc at 419.5°C.

\(^a\) Specific heat capacity measurements by DSC require the use of a well-characterized reference material (usually sapphire) to obtain results. This table summarizes specific heat capacity data (literature values) for sapphire as a function of temperature. These values can be used in the required calculations.

\(^b\) The values in the table were determined by Ginnings and Furukawa of the National Bureau of Standards in the form of synthetic sapphire (corundum). The sapphire pieces passed a #10 sieve but were retained by a #40 sieve, and had 99.98–99.99% purity by weight. Heat capacity values below the experimental range were obtained by extrapolation of the Debye equation fitted to the experimental value at the lowest temperature. The units (J g\(^{-1}\) mol\(^{-1}\)°C\(^{-1}\)) are absolute joules per degree per gram mole (molecular weight, 101.9613) at a constant pressure of 1 atm (100 Pa).
For a comprehensive list of available standards, see Table 1.

2.19 Specific Heat Capacity by Differential Scanning Calorimetry and Modulated Temperature Differential Scanning Calorimetry

There is an ASTM method, E-1269-95, that covers the determination of specific heat capacity, $C_p$, by conventional DSC.\(^{74}\) It is applicable to thermally stable solids and liquids. The normal operating range of the test is from $-100$ to $600^\circ$C. The total DSC heat flow of an empty sample and reference pan is measured. The $C_p$ is determined from the empty pan heat flow profile and the sample heat profile from the thermal curve. Subtraction of these two thermal curves, sample minus the empty pan, will give $C_p$ as a function of temperature. A sapphire standard is used as the calibrant. It is best to evaluate the multiple heat flow responses to sapphire, in order to determine the precision and accuracy of this method, see Table 6.

Measurements of the $C_p$ by the MTDSC method are direct; that is, the specific heat varies linearly over the desired temperature range.\(^{75,76}\) When determining $C_p$ by MTDSC, calibrate the cell with sapphire every $10^\circ$C and correct the reversing heat flow output (the calorimetric portion of the total heat flow). A high-molecular weight NIST PS standard is used to verify the sapphire calibration. The repeatability of the $C_p$ measurement is 2–5% of the value at a specific temperature.

3 APPLICATIONS

Some of the DSC and DTA applications reviewed are based on physical and chemical properties of materials. Melting temperature and heat of fusion, crystallization temperature and heat of crystallization, specific heat capacity of polymers, and curing will be included.

3.1 Alkane Structure–Property Relationships by Differential Scanning Calorimetry, Thermal Microscopy and X-ray Diffraction Analysis

DSC and thermal microscopy helped define a commercial product composed of normal alkanes that was involved in a major law suit.\(^{77}\) The solid-state structures of a number of alkanes have unique crystal structures. These alkanes melt and crystallize below room temperature at more than $60^\circ$C below zero, see Figures 27 and 28. Mixtures of specific alkanes have attributes of pure chemicals, the X-ray diffraction structure (XDS) was very similar, but the melting and crystallization temperatures were statistically different from those expected, see Table 7. The XDS, Miller Index $d$ (002) of a number of even carbon number normal alkanes was linearly related to the corresponding melting and crystallization temperatures, see Figure 29.

3.2 Oxidative Behavior of Materials by Standard and Pressure Differential Scanning Calorimetry: Polymers and Engine Oils

Fundamental knowledge of the oxidative properties of commercial oils is necessary to predict the stability of these fluids. A primary tool to determine the oxidation of fully formulated motor oils, greases, diesel oils, transmission fluids and vegetable oils is DSC and PDSC.\(^{60}\) A diluted motor oil was used to establish experimentally designed relationships between the DSC variables and the OIT,

Figure 30 OIT at constant pressure and variable temperature.

Figure 31 OIT at constant temperature and variable pressure.

Figure 32 OIT by PDSC.

The variables used to develop this protocol were temperature, pressure, heating rate, sample mass, gas flow.
rate, and gas type, air or oxygen. The DSC pan metallurgy played a statistically significant role in the measured OIT. Quality control charting of the DSC oxidation process discovered an out-of-control problem that was related to the impurities in the aluminum pans, see Figure 33 and Table 8. Iron impurities caused a decrease in the OIT of the reference fluid, while the presence of chromium stabilized the oxidation process. A costly engine test can be predicted when a new fully formulated oil blend is examined by PDSC using the OIT protocol, see Figure 34 and Table 9.

Oxidative behavior of commercial engineering plastics, polyolefins and elastomers were evaluated by DTA, TGA and PDSC. There is a good correlation between the measured stability by PDSC in oxygen (ASTM E-1858, OIT) and DTA/TGA (ASTM E-2009, OOT) in air for olefin polymers, see Figures 35–39. The thermooxidative properties of the polymers studied were reliable and precise.

3.3 Inorganic Reactor Deposits by Differential Thermal Analysis, Thermogravimetric Analysis and X-ray Diffraction Analysis

Ash deposits on heat exchange tubes were characterized by DTA, TGA and X-ray diffraction methods. The ash samples were deposited at different locations in the atmospheric fluidized bed combustor system at the TVA Shawnee Steam Plant, Paducha, KY (Figure 40). DSC aided in the identification of the endothermic and exothermic behavior of the deposits and helped develop the mechanism that promotes deposits. The major compound in the deposits from the convention pass inlet, superheater and multclone inlet was calcium sulfate, CaSO₄. The predominant minor component was calcium oxide, CaO. The combined thermal and X-ray techniques are useful for profiling and identifying an unknown ash sample.

3.4 Polymer Characterization by Thermogravimetric Analysis, Differential Thermal Analysis/Differential Scanning Calorimetry, Thermomechanical Analysis, Fourier Transform Infrared and X-ray Diffraction Analysis

A diverse set of commercial polymers were characterized by TGA/DTA, DSC, thermomechanical analysis (TMA), Fourier transform infrared (FTIR) spectroscopy and X-ray diffraction analysis.\(^{79}\) The DSC and DTA were used to document the polymer melting temperature.
Polyolefin melt temperatures by DSC, DTA and TMA were very comparable, see Table 10.

3.5 Assignment of the Glass Transition Temperature

Assignment of the glass transition temperature was the focus of an ASTM conference and special technical publication. R. Seyler, who was the editor and conference chairperson, lead the discussion on the $T_g$. His observations on DSC and DTA are summarized here: a consistently assigned $T_g$ will vary because of differences in heating rate; composition, both chemical and physical, will cause the $T_g$ to vary; diluent and fillers in a specimen usually affect the $T_g$. Moisture is particularly troublesome in $T_g$ measurements. There were many calorimetric contributions to the assignment of the $T_g$ of polymers.

3.6 Copolymer $T_g$ and Molecular Weight

Wunderlich\(^{(81)}\) pointed out that the breadth of the $T_g$ in copolymers varies with molecular mass, see Figure 41.

3.7 Polymer $T_g$ and Moisture

Bair\(^{(82)}\) demonstrated the effect of water on the $T_g$ of polyvinyl acetate (PVAc); the $T_g$ was lower with the addition of 1.5 wt% water, Figure 42.

3.8 Effect of High-pressure Gases on the Polymer $T_g$

Some representative calorimetric curves for PS and ethylene, C\(_2\)H\(_4\), under various pressures can be seen in Figure 43\(^{(83)}\).

**Figure 43** Some representative calorimeter outputs for PS–C\(_2\)H\(_4\) scanned under various pressures (O’Neill).

**Figure 44** DSC curve of the $T_g$, crystallization and fusion of a PET sample quenched in liquid nitrogen (Wiedemann).

**Figure 45** Thermal curves of a copolyester liquid crystal polymer, showing the use of indium as an internal standard (Cassel and Riga).
3.9 Polymer $T_g$, Crystallization and Fusion
Wiedemann$^{(84)}$ presented various thermal techniques in measuring the $T_g$ in polymers, including a DSC curve of the $T_g$, crystallization and fusion of PET quenched in liquid nitrogen, Figure 44.

3.10 Liquid Crystal Polymer $T_g$ and Internal Reference
Cassel and Riga$^{(85)}$ contributed a thermal curve of a copolyester liquid crystal polymer, showing the use of indium as an internal reference standard, Figure 45.

3.11 Polymer Film $T_g$ and Thermal History
Moscato and Seyler$^{(86)}$ studied PET films oriented uniaxially without constraint: see Figure 46, first thermal cycle and second thermal cycle.

3.12 Effect of Inhibitors on Vinyl Monomer Polymerization
DSC$^{(87,88)}$ has been used to study the polymerization of vinyl monomers, acrylamides and acrylates and the effect of free radical inhibitors. Selection of the optimum inhibitor and concentration was based on the exothermic autopolymerization of the monomers. The autopolymerization temperature was proportional to the concentration of a given inhibitor, for example, para-methoxyphenol or $t$-butyl pyrocatechol, Figure 47.

3.13 Differential Scanning Calorimetry “Fingerprint” Curve Identifies Unknown
If you have an unknown material, a polymer or an excipient and drug mixture, DSC can give you vital physical and chemical information about it. In general, a DSC curve has many clues that will lead you on
a path to identification or a better understanding of your material. The DSC, in summary, can supply the $T_g$, crystallization temperature, heat of fusion and/or crystallization, crosslinking (cure) and oxidation or decomposition, Figure 48.

If you have a failed polymer, a DSC curve can reveal the $T_g$ and melt temperatures, but can also suggest prior history of the part, Figure 49.

Endothermic process ordering or exothermic stress relief can be obtained from data surrounding the $T_g$. From low temperatures, below the $T_g$, a material is hard and brittle and above the $T_g$ flexible and elastic. Upon further heating, the polymer is deformable, viscous and finally it reactively deteriorates or degrades. The $T_g$ of thermoplastics, PS and PC are distinguishable from the elastomeric $T_g$ of PBD and SBR, Figure 50. Two immiscible polymers, with a $T_g$ difference between the two homopolymers or copolymers of greater than 10°C, have two $T_g$ values, Figure 51.

3.14 Curing and Polymerization of Thermoset Polymers

Incomplete polymerization of an epoxy resin, thermoset polymer, can yield a lower than expected $T_g$, for example, 77.1°C, Figure 52. However, continued heating of the polymer reveals an exothermic polymerization at 149°C with an exothermic heat of 20.4 J g$^{-1}$. Upon cooling and reheating the epoxy had a higher $T_g$ at 110.5°C. The glass transition temperature of another thermoset polymer varied with cure time and temperature, Figure 53. It is obvious from the plot that the polymer is cured in 20–40 min (plateau in the $T_g$ versus cure time curve) at 175°C, and does not reach cure even at 70 min at 140°C.

![Figure 50] Polymer glass transition temperature by MTDSC.

![Figure 51] Immiscible polymer blend versus homopolymer by MTDSC.
3.15 Polymer Fabrics Identified by Differential Scanning Calorimetry

Hall and Cassel(90) identified fabric material by DSC. Rayon, cotton and wool underwent dehydration and degradation reactions at different temperatures. The DSC “fingerprint” curves clearly distinguished a polyester, polyester–cotton blend and cotton, Figure 54.

3.16 Pharmaceutical Applications: Purity, Polymorphism, Excipients and Lubrication

The DSC is also a problem-solving tool in pharmaceutical applications.(89) First, the purity of C₈H₉BrO₃ is determined from the melting peak and software using the Van’t Hoff melting depression equation. This chemical was found to be 99.43% pure, heat of fusion was 90.9 $\text{J g}^{-1}$ and the melting temperature was 114.8 °C, Figure 55. ASTM E-0928 is the standard test method for mole percent impurity by DSC.(91) This protocol which is based on the melting temperature range of a compound, broadens as the impurity level rises. Results obtained from this method include sample purity (in mol%), enthalpy of fusion (in J mol⁻¹) and the melting temperature (in Kelvin) of the pure form of the major component. The

Figure 52 $T_g$ and polymerization of an epoxy resin.

Figure 53 Variation of glass transition temperature with cure time and temperature.

Figure 54 Identification of (a) fabric materials by DSC and (b) blend samples. (After Cassell and Hall.(90))
single instrument repeatability of purity at a 95% confidence level is that two results should be considered suspect if they differ by more than 0.19 mol%. The multiple instrument reproducibility at a 95% confidence level is that two averages should be considered suspect if they differ by more than 0.72 mol%.

Another pharmaceutical DSC application is the separation of polymorphs. A 4.8-mg sample was heated at 2 °C min⁻¹ from room temperature to 100 °C. Two endothermic peaks are seen at 80 °C and 85 °C corresponding to the transition of each polymorph. The enthalpy of polymorph 1 is 141.0 J g⁻¹ and polymorph 2 is 78.2 J g⁻¹, Figure 56. The approximate composition of the mixture is 64% polymorph 1 and 36% polymorph 2. The actual composition was 52% polymorph 1.

The melting of a pharmaceutical suppository excipient (42.3 mg) was measured from −20 to 55 °C at 2 °C min⁻¹. The thermal curve shows a very broad endothermic peak of melting from 0 to 45 °C. The multiple peaks are due to the melting of the different fatty compounds in the composition of the suppository excipient, see Figure 57.

DSC analysis of a pharmaceutical lubricant is seen in Figure 58. The sample, Sterotex, with a mass of 7.40 mg was heated from ambient to 150 °C at 10 °C min⁻¹. A broad endothermic peak occurred from 44 to 100 °C with an enthalpy of fusion of 88 cal g⁻¹. Superimposed on the broad peak were five additional peaks corresponding to at least five melting phenomena. The melting peaks at 48, 56, 61, 66, and 72 °C correspond to melting of different fatty compounds in the lubricant. If the components were paraffin in nature then the melt temperatures correspond to compounds with greater than 30 carbon atoms or a molecular mass of about 400 g mol⁻¹.

3.17 Food Application: Cocoa Butter

A food application of DSC is the melting analysis of cocoa butter, Figure 59. An 11.1-mg sample was first heated to 50 °C at 10 °C min⁻¹, then cooled to −10 °C at 5 °C min⁻¹ and finally heated to 60 °C at 5 °C min⁻¹. This DSC scheme of heating–cooling and reheating
was to impart a known thermal history to the cocoa butter. The cooling experiment shows an exotherm of crystallization, 67 J g\(^{-1}\) at 17.4–12.3 °C. The final heating cycle had a melt range of 15.4–22.4 °C with a 77 J g\(^{-1}\) heat of fusion. The cocoa butter slightly supercooled based on different melt and crystallization temperatures. The melting crystallization is almost reversible with the heats of crystallization and fusion being 67 and 77 J g\(^{-1}\), respectively. Melting and crystallization heats and temperatures have been observed to be the same, approaching equilibrium values, when the ramp rate is 1.0–2.0 °C min\(^{-1}\).\(^{77}\)

3.18 Biochemical Application: Ribonuclease

A biochemical use of DSC is the denaturation of ribonuclease, Figure 60.\(^{8}\) The sample is ribonuclease A from bovine pancreas. A solution of 2% of the ribonuclease is prepared in 0.2 mol L\(^{-1}\) of glycine and 0.2 mol L\(^{-1}\) of NaCl. The sample mass is 17.7 mg and scanned at 0.3 °C min\(^{-1}\) from 25 to 95 °C. The endothermic denaturation starts at 49.2 °C with a peak maximum at 56.1 °C and an enthalpy of reaction of 389 kJ mol\(^{-1}\). The specific heat capacity variation measured before and after the denaturation is 3.3 kJ mol\(^{-1}\) °C\(^{-1}\).

3.19 Hazardous Material: Aromatic Nitro Compound

Decomposition of an aromatic nitro command is easily detected by a DSC curve, Figure 61.\(^{89}\) A stainless steel container was used with a 5.4-mg sample. The ramp rate was 2.0 °C min\(^{-1}\) from ambient to 330 °C. The nitro compound melts below 50 °C and exothermically decomposes from 200 to 273 °C. The kinetics of decomposition can be estimated when the ramp rate is varied. An ASTM test method, E-0698 can be used to determine Arrhenius kinetic constants for thermally unstable materials by DSC or DTA.\(^{92}\) The Arrhenius parameters combined with the general rate law and the exothermic heat of reaction can be used for the determination of thermal explosion hazards. The accuracy of the kinetic constants is checked by an isothermal aging procedure. A difference of less than 10% relative between predicted and observed results, can be considered a reasonable test of accuracy.

3.20 Characterization of Inorganic Compounds

The dehydration of calcium sulfate hydrate, CaSO\(_4\).2H\(_2\)O can be resolved by DSC, Figure 62.\(^{89}\) A 34.7-mg sample is heated in a closed pan and lid system. The sample is heated at 5 °C min\(^{-1}\) from ambient to 250 °C. The dehydration occurs in two steps. In the first step CaSO\(_4\).1/2H\(_2\)O, hemihydrate is formed with the loss of 1.5 mol of H\(_2\)O. In the second step, CaSO\(_4\), anhydrite is formed with the loss of 1/2 mol of H\(_2\)O. TGA of mass loss as a function of temperature or time, can further study this application.

4 SUMMARY

DSC and DTA are invaluable research, quality control and performance measuring tools. It is easy to run a DSC or DTA experiment and interpretation is usually straightforward. There is an increase in the use of thermal analytical instruments in undergraduate and graduate college and university laboratories. This will result, eventually, in an increased use of DSC, MTDSC and DTA in industrial applications.

5 RESOURCES

The North American Thermal Analysis Society and the International Congress on Thermal Analysis and Calorimetry are resources for scientists seeking a high level of understanding and use of the many thermal analysis methods. ASTM Committee E-37 on Thermal Measurements is the source of standardized thermal analysis procedures, as well as new method development.

6 AMERICAN SOCIETY FOR TESTING AND MATERIALS METHODS USED IN DIFFERENTIAL SCANNING CALORIMETRY AND DIFFERENTIAL THERMAL ANALYSIS

- **D-3418**, 08.02, Standard Test Method for Transition Temperatures of Polymers by Thermal Analysis – This test method covers determination of transition temperatures of polymers by DTA and DSC. First-order transition temperatures or melting points of semicrystalline polymers may also be determined or approximated by the procedures found in D-2117 and D-789. The normal operating temperature range is from cryogenic region to 600 °C.

- **D-4591**, 08.03, Test for Temperatures and Heats of Transitions by DSC (fluoropolymers) – This test method defines conditions for the use of DSC with fluoropolymers: polytetrafluoroethylene, polyvinylidene difluoride, PCTFE and PVF and their copolymers. This test method is applicable to the analysis of powders as well as samples taken from semifinished or finished products.

- **D-5028**, 08.03, Test for Curing Properties of Pultrusion Resins by DSC – This test method covers determinations of curing parameters of pultrusion resins by DSC. The normal operating temperature range is from 0 to 200 °C.

- **D-3895**, 08.02, Test for OIT of Polymeric Materials by DSC – This test method outlines a procedure for the determination of the OIT of polymeric materials by DSC. It is applicable to polyolefin resins that are in a fully stabilized/compounded form.

- **D-4816**, 05.03, Test for Specific Heat Capacity of Aircraft Turbine Lubricants by DSC.

- **D-5483**, 05.03, Test for OIT of Lubricating Greases by PDSC.

- **D-4419**, 05.02, Test for Transition Temperatures of Petroleum Waxes by DSC.

- **E-0472**, 14.02, Standard Practice of Reporting Thermoanalytical – This practice is for general use in reporting experimental information from DTA, TGA, evolved gas analysis or detection and TMA studies. It incorporates laboratory practice with some of the specific needs in thermal analysis. These specific needs account for possible variations of the observed curve with the several parameters reported. Without changing the observed data, reporting in full the conditions under which the data were taken will enable another worker to reconcile differences that may be apparent in another study.

Accompanying each TMA record should be: identification of substances, a statement of source of all substances, a statement of the temperature environment of the sample, identification of the sample atmosphere, statement of geometry, dimensions and materials of sample holder and identification of the abscissa scale in terms of time or temperature.
E-0473-94, 14.02, Standard Definitions of Terms Relating to Thermal Analysis – This standard is a compilation of definitions used in thermal analysis. A definition is a single sentence with additional information included in the notes. It is reviewed every five years.

E-0537, 14.02, Thermal Stability by DTA and DSC.

E-0698, 14.02, Test for Arrhenius Kinetic Constants of Thermally Stable Materials using DTA and DSC.

E-0793-95, 14.02, Standard Test Method for Heats of Fusion and Crystallization by DSC – This test method covers the determination of the enthalpy (heat) of fusion (melting) and crystallization by DSC. This method is applicable to solid samples in granular form or in any fabricated shape from which an appropriate specimen can be cut, or to a liquid sample that crystallizes within the range of the instrument. The normal operating range is from −120 to 600 °C. This method is applicable to thermally stable materials with well-defined endothermic or exothermic behavior.

E-0794-95, 14.02, Standard Test Method for Melting and Crystallization Temperature by Thermal Analysis (DSC and DTA) – This test method covers the determination of melting and crystallization temperatures of pure materials by DSC and DTA. It is applicable to thermally stable materials with well-defined melting temperatures.

E-0928, 14.02, Standard Test Method for Mole Percent Impurity by DSC – This method covers the determination of purity by use of DSC and evaluation of the results using the van’t Hoff equation. Determination of purity by this method is only applicable when the impurity dissolves in the melt and is insoluble in the crystal.

E-0967, 14.02, Standard Practice for Temperature Calibration of DSC and DTA analyzers – This practice covers the temperature calibration of DSC and DTA analyzers over the temperature range −40 to +2500 °C.

E-0968, 14.02, Standard Practice for Heat Flow Calibration of DSC – This practice covers the heat flow calibration of differential scanning calorimeters over the temperature range from −130 to +800 °C.

E-1142, 14.02, Terminology Relating to Thermophysical Properties – This is a compilation of terms and corresponding definitions commonly used in the study of thermophysical properties. Terms that are generally understood or defined adequately in other readily available sources are either not included or their sources are identified.

E-1269-95, 14.02, Test Method for Determining Specific Heat Capacity by DSC – This method covers the determination of specific heat capacity by DSC. It is applicable to thermally stable solids and liquids. The normal operating range of the test is from −100 to 600 °C.

E-1356-95, 14.02, Test Method for Glass Transition Temperatures by DSC or DTA – This method covers the determination of the glass transition temperature, \( T_g \), of materials using DSC or DTA. It is applicable to amorphous materials or to partially crystalline materials containing amorphous regions that are stable and do not undergo decomposition or sublimation in the \( T_g \) region.

E-1782-96, 14.02, Test Method for Determining Vapor Pressure by Thermal Analysis – This method covers a procedure for the determination of the vapor pressure of pure liquids or melts from boiling measurements made using DTA or DSC instrumentation operated at different applied pressures. It may be used in the temperature range 273–773 K (0–500 °C) and for pressures between 5 and 2 MPa.

E-1858-97, 14.02, Test Method for Determining OIT of Hydrocarbons by DSC (PDSC) – This test method covers the procedure for determining the oxidative properties of hydrocarbons by DSC or PDSC and is applicable to hydrocarbons that oxidize exothermically in their analyzed form.

This standard reviews two test methods: A, a DSC is used at ambient pressure, for example, about 100 kPa of oxygen and B, a PDSC is used at high pressure, for example, 3.5 MPa (500 psig) oxygen.

The test specimen in an aluminum pan and the reference aluminum pan are heated to a specified constant test temperature in an oxygen environment. Heat from the specimen is monitored at an isothermal temperature until the oxidative reaction is manifested by heat evolution on the thermal curve. The OIT, a relative measure of the oxidative stability at the test temperature, is derived from data recorded during the isothermal test. The OIT measurement is initiated upon reaching the isothermal test temperature.

E-1860-97, 14.02, Test Method for Elapsed Time Calibration of Thermal Analyzers – This method covers the calibration or performance confirmation of the elapsed time signal from thermal analyzers.

E-1952-98, 14.02, Test Method for Thermal Conductivity and Deriving Thermal Diffusivity by Modulated Temperature DSC.

E-2009-99, 14.02, Test OOT of Hydrocarbons by DSC – This method covers the procedure for
determining the oxidative properties of hydrocarbons by DSC or PDSC and is applicable to hydrocarbons which oxidize exothermically in their analyzed form. In test method A, a DSC is used at ambient pressure, for example, 0.1 MPa or 1 atm of oxygen. In test method B, a PDSC is used at high pressure, for example, 3.5 MPa (500 psig) oxygen.

Thermal Analysis (Volume 15)
Thermal Analysis: Introduction

REFERENCES

89. Setaram, Caluire, Cedex, France, Private Communication, 1999.
The principle techniques chosen for these purposes are associated with the measurement of different properties as a function of temperature and time. Thermogravimetry (TG), thermomagnetometry (TM), and evolved gas analysis (EGA) are based on changes in weight and analysis of the materials evolved or consumed. Differential thermal analysis (DTA) and differential scanning calorimetry (DSC) are concerned with changes in temperature and heat capacity. Thermodilatometry (TD) measures changes in length or volume. Examples illustrating the use of each of these techniques are described.

1 INTRODUCTION

Analysis is taken in its broadest sense to include the characterization of processes and properties as well as the traditional chemical analytical context. In this regard thermoanalytical methods are an exceptionally versatile collection of techniques suitable for a very wide range of applications and materials. Other contributions to this section deal with the instrumentation and methodology associated with the major techniques. Consequently, those aspects will only be considered further when additional information is desired for the specific application under discussion. A substantial number of thermoanalytical applications are in the fields of polymers, pharmaceuticals, and biochemistry. These applications are discussed elsewhere.

Thermal methods encompass a very wide range of techniques and properties, but only the major techniques are considered here. In keeping with this constraint, some modern nontraditional time–temperature programs are not discussed. Approaches such as dynamic temperature and controlled rate techniques are not described in detail, however the reader should be aware of their advantages. Dynamic temperature methods use a nonlinear heating or cooling program that provides periods of both heating and cooling in a prescribed manner. This occasionally enables kinetically reversible events to be resolved from those that are irreversible in either a kinetic or thermodynamic sense. Controlled rate methods utilize feedback from the measurement of the property as a function of temperature to control the temperature program. These methods can offer better resolution of overlapping events and/or a saving in the time required for the experiment.

The range of inorganic materials is large and examples have been selected to include metals, ceramics, minerals and a variety of inorganic compounds. Applications to processes such as catalysis, crystal growth, and synthesis are described.

Thermoanalytical techniques can be used to characterize a wide range of inorganic materials and processes concerning them. The topics covered involve the measurement of thermal properties, phase equilibria, chemical analysis, and the study of solid-state reactivity. Examples are selected to include applications to metals, ceramics, minerals and a variety of inorganic compounds. Applications to processes such as catalysis, crystal growth, and synthesis are described.

films, and so on. Finally, examples have also been chosen to illustrate some of the less common thermoanalytical methods. The organization of subsequent sections is based on the area of application rather than the thermoanalytical technique. This has been done since it is more in keeping with the purpose of this chapter and also because the specific application frequently needs more than one thermoanalytical method to provide the maximum information and benefits.

2 PROPERTIES OF MATERIALS

The discussion is divided into sections on thermal properties, electrical, magnetic and optical properties, and properties associated with surface area and changes in volume that can be investigated through thermal analysis.

2.1 Thermal Properties

DTA and DSC are concerned with the difference in temperature and the exchange of thermal energy between a sample and an inert reference material, as described in detail by Riga in *Differential Scanning Calorimetry and Differential Thermal Analysis*. Hence, DSC is ideally suited for measurements of such thermodynamic properties as heat capacity, thermal conductivity (difusivity), and the changes in enthalpy associated with chemical reactions and physical transformations. DTA can be used to observe these phenomena in a more qualitative manner.

Riga has described in detail the methodology for the determination of specific heat at constant pressure, $C_p$, by DSC or modulated temperature differential scanning calorimetry (MTDSC). Values of $C_p$ are of great interest for compilations of thermodynamic data of elements and compounds. Changes in $C_p$ as a function of temperature reveal phase transformations. During first-order phase transformations a discontinuity in $C_p$ occurs and hence a change in enthalpy, $\Delta H$, is attributable to the transformation. Second-order transformations, however, lead only to a change in $C_p$ and are distinguished in this manner. Most ferroelectric, magnetic, and glass transformations fall into this category. Figure 1 illustrates examples of these three second-order transformations.

Repeated scans of the congruent composition of lithium niobate are shown in Figure 1(a).\(^3\) The Curie temperature, $T_C$, of the transition is indicated. It shows no indication of temperature hysteresis, even at 20°C min\(^{-1}\). The reproducibility is excellent. First-order and second-order transformations are contrasted in Figure 1(b).\(^4\) The melting of lead is represented by a complete peak and the area under the endothermic peak is proportional to $\Delta H$. The ferromagnetic transformation for nickel is indicated by a step in the curve similar to that in Figure 1(a). Figure 1(c) also presents a DTA scan of multiple transitions.\(^5\) The curve is for a fluoride glass and shows in sequence a second-order glass transition at $T_g$, multiple exothermic crystallizations starting at $T_C$, and multiple endothermic meltings commencing at $T_m$.

Several efforts have been made, with moderate success, to adapt DSC instruments to measure thermal conductivity.\(^6,7\) The newer modulated techniques hold greater promise.\(^1\) Other thermal methods based on laser flash techniques are more common.\(^8\)

2.2 Electrical, Magnetic, and Optical Properties

Thermal analysis is defined as the measurement of a property as it undergoes a programmed temperature...
regime. Clearly, such properties include electrical conductivity, dielectric constant, or Seebeck coefficient; magnetization; and optical transmission, reflection, or emission. Instruments have been designed or modified to investigate all of these properties as a function of temperature.\(^9,10\) Of course, the latter classes of spectroscopy can be expanded to include a much broader energy spectrum than the conventional optical range, that is, from \(\gamma\)-rays (Mössbauer spectroscopy) to acoustic waves (thermosonimetry). Wendlandt has pioneered in the field of dynamic as opposed to isothermal measurements in the areas of electrical conductivity,\(^11\) thermovoltammetry,\(^12\) and reflection spectroscopy.\(^13\) His textbook\(^10\) can be consulted for numerous examples.

TM has been the topic of a tutorial review.\(^14\) In TM a generally weak magnetic field gradient is superimposed on the sample position in conventional TG. Consequently a ferro- or ferrimagnetic substance, below its magnetic transition temperature \((T_C)\), will react by apparently losing or gaining weight depending upon the direction of the field gradient. As the temperature passes through \(T_C\) a dramatic change in the apparent weight will occur.

The purpose of TM is not to determine the magnetic moment or saturation of the material, but simply the qualitative aspect of whether it is magnetic and what its \(T_C\) is. Simultaneous DTA and TM can be used to determine the value of \(T_C\) very accurately.\(^14\) Figure 2 shows the simultaneous TM and DTA curves for a sample containing very pure specimens of lead, nickel, and zinc that have been sufficiently separated in the sample container to prevent their interaction. The onsets of melting for the lead and zinc can be compared with their known values\(^15\) and used to make a correction line of measured versus true temperatures. The correction for the observed \(T_C\), the final loss of magnetic attraction, can be interpolated from the linear correction plot. This revised value of \(T_C\) has now been directly traced to the primary standards which determine the International Temperature Scale of 1990 (ITS90).\(^15\) Consequently materials measured in this manner are proposed as standards for the calibration of the temperature axis in TG. This simultaneous TG/DTA technique is also proposed as the ultimately accurate method of measuring \(T_C\) because of its traceability to ITS90.

### 2.3 Dimensional Properties

The Brunauer–Emmett–Teller (BET) approach of measuring the physisorption of a monolayer of a gas, generally nitrogen, is widely used to determine the surface area of a powder.\(^16\) One of the techniques available to measure this physisorption is TG. The change in mass associated with this process is measured and converted to the number of gaseous molecules adsorbed.\(^17\) A complete adsorption isotherm as a function of partial pressure of the adsorbate can be used to describe the porosity of the material as well.\(^16\)

TD is conventionally used to measure the change in volume, or more often length, of a material as a function of temperature. If there is an effect of atmosphere, such as for grossly nonstoichiometric materials, then it is necessary to control and specify the atmosphere as well as the temperature. The high-temperature superconductors are a good example of this dependence, in this case on the partial pressure of oxygen.\(^18\) Descriptions of dilatometers may be found in most texts on thermal analysis.\(^8,9,19,20\) Conventional instrumentation associated with thermomechanical analysis (TMA), is suitable. A flat-surfaced probe with a small load is used in order not to measure any penetration or softening of the sample. The most common sensor is a linear voltage transformer that provides a signal directly proportional to the change in length, having a polarity indicative of the direction, that is, expansion or contraction. Single-probe measurements measure the change in length relative to the material used to construct the probe and sample support. This is usually fused quartz below 1000 °C and alumina at higher temperatures. There are higher precision models that use two probes and measure the difference in expansion of the sample relative to some standard (having the same length as the sample), such as aluminum, sapphire, tungsten, and so on.

The coefficient of thermal expansion is an important property for many applications, for example, bonding of composite materials, matching thermal expansions of thin films and substrates, maintaining alignment of optical devices, and so on. Results of linear thermal expansion measurements are frequently reported as \(\Delta L/L_{298}\), where \(\Delta L\) corresponds to the change in length from 298 K to the

---

**Figure 2** Simultaneous TM and DTA curves for lead, nickel, and zinc metals at 20 °C min\(^{-1}\) in Ar.\(^{10}\) DTG, differential thermal gravimetry.
current temperature and $L_{298}$ is the length of the sample at 298 K. This is a dimensionless quantity that is often expressed in ppm (parts per million) or as a percentage. The coefficient of thermal expansion ($\alpha$) is the derivative of that curve at the temperature of interest and is reported as ppm or percent per degree.

Most composite materials and single crystals have unequal expansion along different directions, that is, they exhibit anisotropy. When measuring polycrystalline solids it is frequently assumed that the crystallographic axes are randomly oriented, so that some general average or volume expansion is measured. Figure 3 shows thermal expansion curves for a highly anisotropic material, KTiOAsO$_4$ (21). The coefficient of thermal expansion is actually negative along the $c$-axis. An interesting aspect of this material is its second-order phase transformation near 850 °C. This is clearly evident as a change in slope of the thermal expansion, particularly along the $c$-axis.

To disseminate the information more accurately and conveniently, data on thermal expansion are generally fitted to a simple third-order polynomial in temperature. The fitting should not be done through a phase transformation because of the concomitant discontinuity or abrupt change in slope. The coefficient of thermal expansion can then be obtained by simply differentiating the polynomial and substituting the desired temperature.

### 3 PHASE EQUILIBRIA

The phase diagram for a system is the proverbial picture worth ten thousand words. It is the starting point for the characterization of a system, defining the specific phases present at equilibrium as a function of composition, temperature, and pressure. The pressure considered includes not only the total pressure, but also the partial pressure of an active component in the gas phase. Simple transformations such as melting and solid$_1$–solid$_2$ transformations were discussed earlier in section 2.1 (Figure 1). In this section, however, the big picture is assembled over the full range of composition encompassing the specific system. Both DTA and DSC are appropriate for investigating phase transformations. If the primary concern is the temperature at which the events occur, then the simpler DTA approach is entirely suitable. If the $C_p$ or $\Delta H$ of the events are desired as well, however, then DSC is the preferred method.

Pope and Judd (22) provide a nice description of the application of DTA to study generic phase diagrams. Figure 4 illustrates how the DTA or DSC curve evolves for a hypothetical binary phase diagram. (21) The hypo-

![Figure 3](image)

**Figure 3** Thermal expansion of KTiAsO$_4$ along various crystallographic axes (21).

![Figure 4](image)

**Figure 4** Evolution of a DTA curve for a simple hypothetical binary phase diagram: (a) the phase diagram with a line at constant composition; (b) the simple cooling curve along that line; (c) the DTA curve along that line (22).
is drawn at constant composition representing a range of temperature from points w to z. That line crosses the liquidus at temperature x and the solidus at temperature y.

The simple cooling curve on going from point w to z is shown in Figure 4(b). While the material is above the liquidus, i.e. single phase, it cools at a rate depending on the exchange of heat with the surroundings. At point x solid phase B begins to crystallize from the liquid and the heat liberated by this exothermic process slows the rate of cooling. Material B is continuously solidifying as the two-phase mixture cools to the eutectic temperature y. At that point, three phases must coexist, solids A and B plus the eutectic liquid composition. The phase rule allows no degrees of freedom and the temperature must remain constant until one of the phases disappears at y'. On cooling this will be the liquid phase. Further cooling then follows the simple curve associated with the heat exchange of the two-phase mixture with its surroundings.

The DTA or DSC curve associated with this process is illustrated in Figure 4(c). The constant rate of cooling between temperatures w and x provides a constant derivative and hence a horizontal line. At point x the rate of cooling changes dramatically and there is an exothermic excursion. Since the amount of B solidifying decreases with time, that exothermic deflection decreases with time and temperature. At the eutectic temperature, y, the remaining liquid solidifies isothermally, which should give rise to an infinite derivative. This is tempered, however, by the finite kinetics of the process and is reflected as a sharp exotherm in the curve. Finally, the material cools at a nearly constant rate again below temperature y setting up another horizontal section of the curve.

This is extended to a more complex phase diagram in Figure 5 that includes congruently and incongruently melting compounds. A series of cuts are made at key compositions in the system. The corresponding DTA curves, upon cooling, are illustrated directly above their respective compositions. These compositions were selected to indicate the variety of potential curves showing the peritectic point in curves 2 and 3, the simple eutectic in curve 4, and the congruently melting compound in curve 5. Curves 6 and 7 are similar to those in Figure 4. The liquidus curve is traced as the dashed line across the series of DTA curves.

Naturally, a simple collection of cooling curves is insufficient to establish the phase diagram. Supercooling and metastability are frequent problems so that heating curves should be determined and considered as well. Evidence of such kinetic behavior can be obtained by varying the heating and cooling rates. X-ray diffraction (XRD) is needed to establish the structures and, along with the electron microprobe analyses, verify the identities of the phases present in each region. Microscopy of polished sections is helpful for determining small quantities of phases and predicting whether any phases had been liquid at some time during the thermal treatment.

3.1 Metals

Shull discusses applications of DTA to phase transitions and phase equilibria in metals. Particular attention is given to the high-titanium portion of the complex Ti–Al diagram. In this paper, and references therein, detailed DTA studies showing the effects of subtle order ⇔ disorder transitions are outlined. To explain these observations completely, however, as indicated earlier, it was necessary to invoke other measurements, such as high-temperature XRD and various microscopies.

Thermoanalytical techniques are ideally suited to investigate nonequilibrium phenomena as well as equilibrium diagrams. Metastable-to-stable transformations are quite exothermic and frequently occur abruptly once nuclei form. Altounian and Strom-Olsen have reviewed some applications of amorphous to crystalline transformation in alloys. Figure 6(a) shows a DSC scan of initially amorphous Pd40Ni40P20, while Figure 6(b) illustrates the effects of successive annealing periods of 1 h on the crystallization
peaks. The glass transition of the disordered metal is clearly evident near 600 K. There are two sharp exotherms associated with crystallization of two phases at higher temperatures. Annealing at temperatures below \( T_g \), however, will lower the crystallization temperature dramatically and sharpen the peak as well. This is because the values and range of activation energies for the process both decrease as the annealing temperature approaches \( T_g \). Other examples include NiTi alloys\(^{25,26} \) and AlLi alloys.\(^{27} \)

TM can play a role in determining phase equilibria for magnetic materials. The value of \( T_C \) for instance can be used to identify the phases precipitated from metallic glasses, for example FeB and NdFe systems, as well as to follow the kinetics of crystallization.\(^{24} \)

Chromindur alloys (FeCrCo system) offer an interesting example illustrating magnetic effects during spinodal decomposition.\(^{28} \) The very close continuous proximity of the two phases induced by spinodal decomposition allows the magnetic field of the phase having the higher \( T_C \) to clamp and maintain the magnetic alignment of both phases to the higher temperature.

3.2 Ceramics

Thermal analysis, particularly DTA, has played an active role in most determinations of phase equilibria. Establishing the liquidus and solidus portions of the diagram as described in Figure 5 is common. Similarly, determinations of subsolidus phase transformations, as illustrated in Figure 1, are also commonplace. TG, however, offers the added ability to determine the regions of stability as a function of the atmosphere. Variations in phase equilibria are measured as a function of the partial pressure of an active component in the gas phase, such as oxygen, sulfur, halogens, volatile compounds, and so on.

Vapor pressures can be measured using Knudsen cell techniques. The stepwise reduction and volatilities of gallium sulfides were determined through the homologous series from BaGa\(_2\)As\(_4\) to Ba\(_3\)Ga\(_2\)As\(_8\).\(^{29} \) The vapor pressure is constant, but different, in each of the two-phase regions. It changes abruptly to a lower equilibrium pressure of Ga\(_2\)S\(_n\) and S\(_2\) as each member in the series BaS\(_{x}\)Ga\(_2\)S\(_3\) becomes exhausted at constant temperature. These isothermal, isobaric steps define the two-phase regions in the phase diagram.

The degree of oxygen nonstoichiometry controls the electrical, magnetic, and optical properties of materials. For example, the properties of a ferrite depend strongly on the Fe\(^{2+}\) to Fe\(^{3+}\) ratio. Normally this is set during the high-temperature sintering step and then quenched in, as much as possible, to yield a metastable single-phase spinel at room temperature. If the exact oxygen content is known at some point, then the changes in oxygen content can be followed by very careful TG measurements as the temperature and partial pressure of oxygen are varied. Careful work is needed to account for small changes in mass and losses other than oxygen.

Figure 7 shows both raw and processed data for a Ni\(_{0.685}\)Zn\(_{0.177}\)Fe\(_{2.138}\)O\(_{4+\gamma}\) spinel.\(^{30} \) Figure 7(a) shows the raw data achieved after long equilibration times in various partial pressures of oxygen at the indicated temperatures. The changes in mass indicated on the right ordinate are converted to \( \gamma \) in the chemical formula and shown on the left ordinate. The dependency of the results on the direction of crossing the phase boundary illustrates the metastability achieved on passing from the single-phase regime, I, into the two-phase region,
II, when nucleation of a second solid phase must take place. Nucleation is not needed when passing from the two-phase into the single-phase region. The mass axis has been corrected for buoyancy and for the mass losses of ZnO and PtO₂ occurring at the higher temperatures.

Figure 7(b) presents the van’t Hoff plots based on the data in Figure 7(a). The various lines are for the indicated values of $\gamma$ and reflect how the partial pressure of oxygen and the temperature must adjust to preserve a constant composition. The dashed lines represent the metastable situation. Similar work has
been done for several high-temperature superconductors where the desired property depends closely on the oxygen content.\(^{31}\)

### 3.3 Others

Besides the wide array of metallic and ceramic systems, there are many studies of fused salt systems, for example, nitrates, halides, sulfates, hydroxides, and so on. The results of such studies have been compiled, along with oxide-based systems, in *Phase Diagrams for Ceramists*.\(^{32}\) Typical examples of the use of DTA to determine such diagrams are those of Touboul et al.\(^{33}\) for systems of Li$_2$SO$_4$ with several divalent sulfates, Thiel and Seifert\(^{34}\) for alkali halides, and Paulik et al.\(^{35}\) for the many hydrates of Ni(NO$_3$)$_2$. Coupling DSC or DTA with optical microscopy can prove particularly informative. Such techniques have been described by Wiedemann and Felder-Casagrande\(^{36}\) and the NaNO$_3$–KNO$_3$ system used as an example. Similarly the work of Arii and co-workers,\(^{37,38}\) utilizing simultaneous XRD with DSC or TG, provides a valuable tool for studying phase equilibria and chemical reactivity.

### 4 CHEMICAL ANALYSIS

As indicated in the introduction, the general term “thermal characterization” is more appropriate than “thermal analysis”. Nevertheless, there are many instances where thermoanalytical techniques can be used to perform chemical analysis in a convenient, relatively rapid, and accurate manner. Five examples are chosen to illustrate the use of TG, TM, DTA, DSC, and EGA for this purpose.

#### 4.1 Lithium Niobate

The ferroelectric transformation discussed earlier and depicted in Figure 1(a) for Li$_{1-x}$NbO$_3$–$0.5x$ forms a very convenient and accurate way to determine the value of $x$. Large, virtually perfect single crystals of this material are desired for electro-optical devices. The compound melts incongruently and it is necessary to grow the homogeneous crystals from a nonstoichiometric liquid. The exact composition of the congruently melting composition was determined by DTA curves for the second-order transformation, such as those shown in Figure 1(a).

A carefully prepared series of standards was made and measured.\(^{35}\) Figure 8(a) shows the resulting calibration curve for the determination of the Li content based on $T_C$. During crystal growth from these standard compositions by the Czochralski technique, samples were taken from the initial and final melts and the top and bottom of the resulting crystal. From the Li content in these samples it was possible to determine the distribution of Li between the solid and liquid phases. The distribution coefficients are plotted in Figure 8(b).\(^{35}\) The congruent composition is that having a distribution coefficient of unity, 44.85 mol% Li$_2$O. When the crystal is pulled from a melt of that composition, the DTA curves for those four samples, that is, beginning and ending melt and solid, will have the same composition as indicated in Figure 8(c). Not only did this provide the necessary analytical data, it now provides an excellent method for quality control of the incoming cullet and outgoing crystal. A correlation was also made between the value of $T_C$ and various aliovalent substitutions which produce defects similar to that accompanying Li deficiency.\(^{35}\)

#### 4.2 Lead–Tin Solder

A solid-state transition was used for analytical purposes in section 4.1. The liquidus curve can serve that function as well. Kuck\(^{39}\) clearly demonstrated that the onset of a solid phase on cooling, or the onset of liquid phase on heating, could be compared with the phase diagram to establish the composition. Since the binary system forms a simple eutectic similar to that depicted in Figure 4(a), it is necessary to know which side of the eutectic the composition one is on, in order to establish the composition uniquely. Such analyses were used successfully to determine the solder composition of electroplated samples as a function of the various plating conditions.

#### 4.3 Nonstoichiometry

In section 3.2, the use of TG was described to determine variations in the composition for various oxides as a function of the partial pressure of oxygen (see Figure 7). The success of this in terms of absolute composition, however, requires that the exact composition be known at some point in order to convert the relative concentrations to absolute values. Frequently, total or partial reduction of the starting material may be achieved to provide a known composition. Examples of this are for materials such as BaPtO$_3$–\(^{40}\) or Ba$_2$YCu$_3$O$_7$–$\delta$\(^{41}\)

Figure 9(a) presents TG curves for heating samples of Ba$_2$YCu$_3$O$_7$–$\delta$, a high temperature superconductor, in a nonexplosive forming gas (15% H$_2$, 85% N$_2$).\(^{41}\) The thermodynamics of these oxides is such that only copper is reduced and the final elemental composition is Ba$_2$YC$_{\delta}$O$_{3.50}$. Consequently, the overall mass loss at that point can be converted to the value of $\delta$ in the starting material. Once the starting composition has been determined, the changes in mass as a function of the partial pressure of oxygen and temperature indicate the changing composition.
Figure 8 Use of DTA to establish the congruently melting composition of Li$_{1-x}$NbO$_3$–0.5Li$_2$O:
(a) $T_C$ as a function of Li content; (b) distribution curve for lithium between the liquid and solid phase; (c) DTA curves from the starting and ending melts during Czochralski crystal growth and the top and bottom portions of the resulting crystal.

In this instance the changes are large and easily measured. The kinetics of the process are favorable so that measurements can be done in a dynamic manner, as contrasted with the isothermal approach used for ferrites (see Figure 7). The fact that equilibrium is established at the chosen heating or cooling rate can be established by comparing the results with those obtained at isothermal sections. Agreement between the values attained during the heating and cooling stages indicates that equilibrium was established in Figure 9(b). This approach is less viable for other superconducting or catalytic compositions containing, for example, Bi, Pb, Hg, and so on because of the volatility of the metal or its oxide.

4.4 Alloys and Ferrites by Thermomagnetometry

In section 2.2, the use of well-defined magnetic transition temperatures to calibrate the temperature axis during TG was described. Conversely, measured values of $T_C$ can be used to establish the composition in many instances. The use of TM for qualitative analysis during studies of phase equilibria was briefly described in section 3.1. Other examples are covered in section 5.

Haglund has reviewed some quantitative applications in metallurgy. An excellent example is the use of TM to analyze cemented carbide tool steels. Figure 10(a) indicates that $T_C$ is a good indication of the WC content dissolved in the binder phase, Co. Figure 10(b) shows how both the dissolved Ti and C affect the $T_C$ for Ni-based binder systems. The facts that Ni and Co form a complete solid solution and that the end members differ in their values of $T_C$ by about 770°C form a good basis for analysis of Ni–Co alloys. Ferrites having the spinel structure and based on substitutions into Fe$_3$O$_4$ are very difficult to distinguish by XRD. However, the
value of $T_C$ generally has a strong dependence on the extent and nature of the substitution and offers a method of analysis.\textsuperscript{14}

4.5 Thin Films

The small amount of available sample in combination with the large amount of inert material, the substrate, presents a major challenge when analyzing thin films using thermoanalytical methods.\textsuperscript{44,45} Gallagher\textsuperscript{44} and Leskelä et al.\textsuperscript{45} indicate that careful application of the traditional methods can be valuable. However, EGA, particularly by mass spectrometry (MS), is an especially viable technique because of its great sensitivity. Figure 11 summarizes the use of mass spectrometry/evolved gas analysis (MS/EGA) to analyze for key impurities in two thin films of importance in the manufacturing of semiconductor devices. Thin films of TaSi$_2$ are occasionally used as conductors during device fabrication.

These films were prepared by sputtering in a reduced pressure of Ar and adhesion to the substrate was a problem initially. Extensive MS/EGA studies revealed that Ar was incorporated into the films and was evolved at an untimely stage during the subsequent processing (Figure 11a).\textsuperscript{46} Studies of the processing conditions, in combination with characterization of the resulting films by MS/EGA, provided a means of reducing the problem to acceptable levels.

The opaque mask material frequently used in X-ray lithography of silicon wafers is BN. It is prepared by a CVD process involving various hydrogen-containing species, for example, diborane and ammonia. Frequently, H$_2$ is trapped in the thin film of BN and induces substantial mechanical stress therein. The resulting strain distorts the wafer and destroys the ability to align the mask. The broad overlapping peaks in the EGA of such a wafer and film, as shown in Figure 11(b), indicate that the H$_2$ is bound at a variety of sites. Annealing samples at different temperatures for various times to remove H$_2$, followed by subsequent EGA experiments, provided the opportunity to develop a suitable process to relieve the stresses.\textsuperscript{47} Only the less strongly bonded H$_2$ needs to be removed, so a modest anneal at 550°C is sufficient.
Figure 11 MS/EGA plots of electronic materials: (a) TaSi$_2$ films prepared by sputtering in Ar; (b) BN films prepared by chemical vapor deposition (CVD) using B$_2$H$_6$ and NH$_3$.

5 REACTIVITY

This is a very extensive and complex topic having great technological importance. Thermal analysis plays an important role in many ways. The first three subsections divide the topic into qualitative, quantitative, and overall considerations. The next two subsections discuss specific areas of application that have particular industrial importance. All these aspects of reactivity are then focused in the final subsection on the synthesis of materials.

5.1 Solid-state Reactions

Reactions involving solid phases are frequently divided into (1) solid–solid, (2) solid–liquid, and (3) solid–gas reactions. Solid-state decompositions may be considered as a separate class. All four categories lend themselves to thermoanalytical detection. Many solid–solid reactions are examples of acid–base reactions. Consider the equilibria shown in Equations (1) and (2), where the alkaline earth compound is basic, the silica is acidic, and the resulting compound is a salt:

\[
\text{CaO}_{(s)} + \text{SiO}_2(s) = \text{CaSiO}_3(s) \quad (1)
\]

\[
\text{CaCO}_3(s) + \text{SiO}_2(s) = \text{CaSiO}_3(s) + \text{CO}_2(g) \quad (2)
\]

Often reactions such as that shown in Equation (2) take place essentially in a single step without the appearance of a separate stage of carbonate decomposition forming an intermediate, CaO in this case. This is justification for writing the reaction shown in Equation (2) as a single equation.

Equation (1) occurs without a change in mass or the evolution of a gaseous product. Consequently, it is not detected by TG or EGA. No magnetic phases are present so TM is not suitable. The most appropriate thermoanalytical technique involves detection of the heat absorbed or evolved by the reaction, that is, DTA or DSC. XRD is also a viable means of observing the onset of such a reaction as the temperature is raised. Both methods are often used, although, DSC or DTA are far simpler and generally more sensitive. The reaction could also be detected by changes during TD experiments. However, this would be relatively indirect and less easily interpreted. The reaction shown in Equation (2) is amenable to the same methods of detection as that in Equation (1) but, because a gaseous product is formed, it is easily identified by both TG and EGA.

When any of the reactants, intermediates, or products are ferro- or ferrimagnetic it is possible to use TM as a tool to follow the reaction. During the thermal decomposition of many compounds of iron(II) in an oxidizing atmosphere, for example, carbonates or oxalates, the final product is usually an oxide of iron(III). Does an intermediate of mixed valence, for example, Fe$_2$O$_3$ or a related compound form? These spinels have very similar XRD patterns and it is difficult to determine the composition by that method.

Since the spinels containing iron are frequently magnetic, TM curves may be used to detect and identify the particular spinel formed. Figure 12(a) presents the TM curves for the decomposition of a very pure mineral, siderite (FeCO$_3$), in oxygen and nitrogen. The value of $T_C$ for Fe$_3$O$_4$ is about 585°C. The decomposition in oxygen yields Fe$_2$O$_3$ directly without any evidence for the formation of Fe$_3$O$_4$ as an intermediate. However, the TM curve in nitrogen clearly shows a very substantial apparent gain in weight at the onset of the decomposition corresponding to the formation of Fe$_3$O$_4$. The curve returns to the normal weight as the magnetic attraction disappears. The agreement of the final weights in both atmospheres indicates that the oxygen content in “inert”
gases is frequently well above that necessary to preserve the reduced species for long times.

Similar studies on common samples of siderite do not show this magnetic effect during decomposition in an inert atmosphere. It is tempting to conclude that impurities prevent the formation of the intermediate spinel. TM curves during cooling after the decomposition, however, indicate that the magnetic spinel intermediate is formed. Typical metallic impurities in siderite are other divalent cations, such as magnesium and manganese. Figure 12(b) presents TM curves for such partially substituted spinels or ferrites. The values of $T_C$ for such substituted spinels are below the onset temperature of the decomposition and consequently there is no magnetic attraction observed during heating.

![Figure 12](image)

**Figure 12** TM curves obtained at 10 °C min$^{-1}$: (a) very pure siderite in O$_2$ and N$_2$; (b) various substituted spinels and hematite in O$_2$.

The XRD patterns for nickel and cobalt, which have the same structure and nearly identical atomic radii, are very similar. Consequently, it is impossible to determine whether solid solutions of the co-precipitated oxalates decompose in an inert atmosphere to form initially the individual metals or an alloy. A comparison of TM curves for physically mixed and coprecipitated oxalates reveals that the physical mixtures decompose to individual metals while the co-precipitates are more reactive and form the alloy directly.$^{43}$

The two examples so far have been for solid–solid and decomposition reactions. The field of corrosion provides many examples of solid–gas reactions.$^{54}$ Melting and crystallization reactions (solid–liquid) have been described in conjunction with phase equilibria. Clever corrosion studies were performed by Charles$^{55}$ using TM of sealed ampoules containing a ferromagnetic metal and corrosive liquid media. The apparent loss of weight was followed as the metal dissolved.

### 5.2 Heterogeneous Kinetics

Section 5.1 describes following reactions in a qualitative manner. Kinetic studies, however, require a quantitative description of the concentrations as a function of time. Several excellent treatises are available on the heterogeneous aspects of this topic.$^{56,57}$ Heterogeneous kinetics is a far more complex and controversial topic than homogeneous kinetics. Aspects of geometry, sample size, contact among reactants, thermal and mass transfer, structural order, defects, and so on, control the rate more than simple traditional terms related to concentrations.$^{58}$

The conventional expressions for concentration are not useful and the term “fraction reacted” (0 to 1) is commonly used instead. Determining the mechanism of the reaction under these conditions is a demanding task.

The fraction reacted, $\alpha$, can be readily derived from various thermoanalytical measurements provided that certain assumptions are valid. While evolved or consumed, gas analysis is a direct measurement of the progress, and changes in mass or volume and the evolution or absorption of heat are indirect measurements of $\alpha$ predicated on an assumed general mechanism, stoichiometry and a known starting or ending point. In the simplest case, the overall integrated change in the measurement is normally assigned a range of $\alpha$ from zero to unity. The fraction of that total integral is then converted into $\alpha$ as a function of time and/or temperature assuming that the mechanism does not change in the region of interest.

Detailed discussion of kinetic analysis is beyond the scope of this chapter. Figure 13, however, indicates how thermoanalytical data, TG in this case, are used for this purpose. The simple thermal decomposition of NaHCO$_3$
is the example, shown in Equation (3)

\[
2\text{NaHCO}_3(s) = \text{Na}_2\text{CO}_3(s) + \text{H}_2\text{O}_2(g) + \text{CO}_2(g)
\]  

(3)

Isothermal data are presented in Figure 13(a) and examples of dynamic temperature results are given in Figure 13(b).

The change of \( \alpha \) or \( d\alpha/dT \) with time or temperature is then fitted to various rate laws to find the best mathematical description. This process is fraught with uncertainties and caution must be exercised. Decomposition of carbonates and hydrates, redox reactions, or other readily reversible reactions are particularly subject to variability because the removal of the products becomes a factor. Highly exothermic or endothermic reactions are subject to limitations due to thermal transport. It is advisable to vary the experimental parameters, for example, sample size, sample packing or shape, and gaseous flow rate, in a meaningful manner in addition to making other supporting measurements, such as XRD, microscopy, and so on, before making conclusions based on the mathematical analysis regarding the mechanism and significance of the resulting Arrhenius parameters.

5.3 Influences on Reactivity

The previous two subsections described the qualitative and quantitative aspects of following chemical reactions and the effects of temperature upon them through use of thermoanalytical methods. Consider now evaluating the effects of factors other than temperature which influence the nature of solid-state reactions. Anything that introduces defects or structural flaws into the reactants will generally increase their reactivity. Hedvall, in his famous review article, listed these as (1) mechanical deformation; (2) impurities, vacancies, interstitials, and so on; (3) radiation; and (4) changes in crystal structure accompanying phase transformations or decompositions. The last aspect was a new concept and is still controversial. It has been referred to as the “Hedvall Effect”. Radiation is generally considered as optical, X-ray, \( \gamma \)-ray, and so on; however, magnetic or electrical fields may also influence reactivity.

Comparison of the thermoanalytical results for samples that have had carefully specified and controlled pretreatments will frequently reveal factors that influence reactivity. An alternative approach is to measure essentially identical samples under different experimental conditions involving exposure to fields or radiation, oxidizing or reducing atmospheres, or during phase transformations. Figure 14 shows examples of each of these three conditions based on thermoanalytical measurements.

In Figure 14(a) UV radiation is turned on at different stages during the isothermal decomposition of AlH\(_3\). Clearly the rate of the reaction increases dramatically upon radiation. Figure 14(b) indicates how lowering the partial pressure of oxygen enhances the reaction of BaCO\(_3\) with Y\(_2\)O\(_3\) and CuO to form the high temperature superconductor Ba\(_2\)YCu\(_3\)O\(_{6+x}\). The lower oxygen pressure leads to a larger value of \( x \), which in turn raises the diffusion coefficients of the reactants through the product layer separating them. The “Hedvall Effect” is illustrated in Figure 14(c) where the rate for the oxidation of magnetite is altered substantially in the region of the magnetic phase transition of the reactant, Fe\(_3\)O\(_4\).

5.4 Heterogeneous Catalysis

Many commercially important processes are only viable because of the successful development of heterogeneous
catalysts. The catalytic action is based on surface active sites. These sites are generally chemically specific in nature such as acidic or basic, oxidizing or reducing, etc. Frequently the number and nature of such sites are determined by adsorption or desorption of specific gases. Acidic and basic sites can be determined from TG curves using suitable gaseous adsorbents, e.g. NH₃ for acidic sites or HCl for basic sites. Thermal desorption experiments are a common form of EGA. The temperatures at which various chemisorbed species are released or adsorbed from the catalyst is highly informative.

Most reactions have a substantial change in enthalpy associated with them. This evolution or adsorption of heat can be detected calorimetrically or by DTA. The oxidation of CO is very exothermic and can be rapidly and conveniently studied by DSC. These measurements require little sample and are simpler than conventional catalytic reactors for surveying potential catalysts and poisons. The DSC signal exhibits excellent correlation with analytical results for the progress of the reaction.

Some examples are depicted in Figure 15 for the oxidation of CO using supported oxide catalysts. Figure 15(a) shows DSC curves at 10°C min⁻¹ for a flow of 2% O₂, 2% CO, and 96% N₂ over various catalysts. The earlier the temperature rise the more efficient the catalyst is. The unfortunate poisoning of the catalyst by as little as 150 ppm of SO₂ is indicated in Figure 15(b). If Pt is used in place of the oxide as a catalyst, the reaction is oscillatory in nature and the resulting temperature excursions can be followed by DSC under the right circumstances. Another example is the work of Kosak utilizing DSC at high pressure to follow the hydrogenation of unsaturated organic material using supported precious metal catalysts.
5.5 Sintering

Most ceramic materials require a sintering step in order to achieve the desired mechanical, electrical, or magnetic properties. There is no change in mass associated with sintering and the process is so slow that the small evolution of heat accompanying the decrease in surface energy is not readily detected by DSC or DTA. The consolidation, however, leads to an increase in density and a decrease in volume. The latter is generally measured along a direction of interest by TD.

The change in length will exhibit discontinuities at first-order phase transformations and changes in slope at higher order transformations. Thermal decompositions may lead to expansion when gaseous products evolve. Sintering or densification is detected as a shrinkage. All these effects, plus the intrinsic thermal expansion of the sample, occur simultaneously and the observed TD trace is a composite of overall process. Figure 16 shows TD traces for the sintering of BaTiO₃. The shrinkage curves are shown directly in Figure 16(a).

The derivatives of these curves, that is, the rates of shrinkage, are depicted in Figure 16(b) and more clearly indicate the multiple stages that occur in these samples. These steps may arise from many causes, for example, density gradients in the powder compact, heterogeneous particle-size distribution, the presence of impurities, reactions with the atmosphere or support, variations in the reactivity of the powder, and so on.

This is particularly an auspicious point to mention briefly applications of unconventional temperature programs. Controlled-rate TD shows promise for achieving improved sintering while also conserving energy. The pioneering works of Palmour and Johnson on the sintering of alumina and the recent work by Agarwal and Speyer on other oxides are notable.

Dynamic temperature TD may offer the opportunity to resolve some of the overlapping events accompanying sintering that were mentioned in the preceding paragraph.
5.6 Synthesis

All the factors discussed under phase equilibria and reactivity are relevant when considering the synthesis of solid-state materials. The fundamental goals are to control, for each product, the

- chemical and phase composition
- macroscopic and microscopic morphology
- subsequent reactivity and stability.

It may also be necessary to control carefully the extent of the reaction, either to completion or to a limited extent when the desired product is an intermediate.

Traditional methods of synthesis involving solid₁ plus solid₂ reactivity have been discussed. However, many modern methods of solid-state synthesis for ceramics, electronic materials, alloys, catalysts, and so on involve the thermal conversion of precursors. These precursors are generated from co-precipitates, spray-dried or freeze-dried powders, sol-gels, and so on.\(^{(72)}\)

Thermoanalytical methods are the primary tools for the characterization of the conversion process. Figure 17(a) shows an example of the use of TG to follow the thermal conversion of BaTiO\((\text{C}_2\text{O}_4)_2 \cdot 4\text{H}_2\text{O}\) into BaTiO₃\(^{(73)}\)

Figure 17(b) uses DSC to follow the ignition temperature of a spray-dried mixture leading to a high temperature superconductor\(^{(74)}\) and Figure 17(c) uses EGA to follow the burnout of the plastic binder in a tape-cast superconducting composition\(^{(9)}\). Information from such experiments provides the basis for processing such precursors. TD provides the basis for subsequent sintering of the powders to dense, useful products.

6 CONCLUDING REMARKS

It was established in the introduction that space limitations would constrain the discussion to but a handful of the potential applications utilizing the major techniques. It is hoped that the selection herein will have served to point the way to further consideration and investigation by the reader. General references have been provided that are intended to encourage the reader to delve into the less common methods, such as those involving various forms of spectroscopy, acoustic emission or absorption, dielectric properties, and so on. Similarly the more sophisticated use of feedback and nonlinear programming is markedly improving the interpretation of the results and extending information achievable. The limits to applications of thermal methods are those imposed by our imaginations and ingenuity.

Simultaneous Techniques in Thermal Analysis

David Dollimore and Pauline Phang
The University of Toledo, Toledo, USA

1 INTRODUCTION

While single techniques in thermal analysis are often used to analyze the thermal characteristics of a sample, there is an increasing preference for the application of coupled techniques. The operation of coupled techniques provides an analyst with a more comprehensive picture of the sample which is being investigated. For example, from a differential thermal analysis (DTA) trace, an analyst will be able to identify the various endothermic and exothermic reactions that are occurring as a sample undergoes the prescribed thermal treatment. However, it would be extremely useful if the analyst could also determine if the reactions corresponded to either physical or chemical changes. A thermogravimetry (TG) trace would show the physical and chemical changes for a sample as it undergoes heating. Hence, the coupling of these two thermal techniques would lead to a more complete profile of the material that is being analyzed.

When two analytical techniques are coupled and employed on any given sample within a single run, the term ‘simultaneous’ is used to refer to this procedure. Very often, the coupled thermal techniques, such as TG/DTA (simultaneous thermogravimetry and differential thermal analysis), are also referred to as ‘hyphenated techniques’. It would be prudent to mention that the term simultaneous is not to be confused with the terms ‘combined’ or ‘consecutive’. Both of these terms refer to either the investigation of a material by running independent samples on different instruments or on different arrangements of the same instrument.

In this article the theory, operation and applications of a TG/DTA system will be explored. It is important to understand the advantages and disadvantages associated with the use of simultaneous techniques. Since the introduction of microcomputers, the inclusion of a computer workstation as an integral part of a thermal analysis operating system has evolved over time. Hence, some consideration will be given to the vital contributions of a computer workstation to a TG/DTA unit. A concise discussion on the various analysis techniques associated with TG/DTA will also be presented. Evolved gas analysis (EGA) is often performed on the gaseous products evolved from a sample that was analyzed on a TG/DTA unit. The methods used to detect and identify these gases include mass spectrometry (MS), Fourier transform infrared (FTIR) spectroscopy and gas chromatography (GC). The ultimate purpose of developing simultaneous techniques is to devise advanced systems which are capable of incorporating various conventional and thermal analytical techniques within a single system.
the instrumentation and the working capabilities of a TG/DTA unit. As with any analytical technique, there are certain strengths and limitations linked with the use of simultaneous techniques. It is essential to know the boundaries of a chosen technique as this will help in the design of the experiments to be conducted.

2.1 History of Simultaneous Thermogravimetry and Differential Thermal Analysis

Due to the rising demand for coupled thermal techniques, simultaneous systems which afforded the collection of TG, derivative thermogravimetry (DTG) and DTA or differential scanning calorimetry (DSC) signals were developed. These units typically comprise thermobalances that are capable of monitoring the mass changes within a sample, and the temperature differences between a sample and reference cell as the sample is being subjected to a controlled temperature regime.

The pioneering TG/DTA system (dubbed the ‘Derivatograph’) involved the use of a derivatograph to allow for the simultaneous collection of TG/DTA data. A schematic diagram of the Derivatograph is presented in Figure 1. The success of the first simultaneous unit spurred the emergence of improved TG/DTA (or DSC) systems such as the Stanton-Redcroft TG/DTA and the Setaram simultaneous TG/DSC. Some latter day manufactured simultaneous systems include the TA Instruments SDT 2960 (TG/DTA) and the Netzsch STA 409 (TG/DSC).

2.2 Instrumentation of Simultaneous Thermogravimetry and Differential Thermal Analysis

As mentioned in the previous section, TG/DTA unit designs are generally based on a thermobalance that is equipped with thermocouple leads. There are two basic arrangements for TG/DTA equipment. The first involves placing the sample and reference cells on one common vertical platform (refer to Figure 2). For this design, there is a single thermocouple that is responsible for the system temperature. The second arrangement entails separate sample and reference cells (see Figure 3). In this set-up, there are two thermocouple leads, and each of them is attached to the base of either the sample cell or the reference cell.

The modern TG/DTA system should consist of the following components. In addition to the microbalance with attached thermocouple leads, there should also be a computer workstation linked to the system. A discussion of the various roles of a computer workstation as linked to a TG/DTA unit, will be presented in the next part of this chapter. Generally, a direct current (DC) amplifier is also included in the system to enhance the DTA signal. Lastly, there should be a recorder to collect the various TG and DTA signals.

In newer models of simultaneous instruments, there are a few variations in the basic design. These changes were incorporated in an attempt to build better simultaneous thermal analysis units. For example, the TA Instruments

2.4 Advantages of Simultaneous Thermogravimetry and mass changes while the sample is being heated. The use of a horizontal double beam balance set-up. The use of a horizontal system was introduced to counteract the effects of purge gas flow into the chamber unit. Yet another variation, the Setaram TG/DSC 111 involves the use of symmetrical dual furnaces linked with Calvet microcalorimeters, while the Netzsch STA 409 (TG/DSC) incorporates the use of a heat-flux panel within the unit.

2.3 Limitations of Simultaneous Thermogravimetry and Differential Thermal Analysis

A fundamental design limitation of the TG/DTA technique is that the sensitivity of both the TG and DTA methods are somewhat reduced when coupled. In practice, small sample sizes and fast heating rates are the recommended experimental parameters if one desires to achieve well-resolved DTA curves. This is necessary to ensure the rapid development and loss of temperature gradients as the sample is subjected to heating. Conversely, in order to enhance the output from TG experiments, large sample sizes and slower heating rates are advocated. Thus, a compromise has to be enforced if an analyst wants to optimize both signals from the TG/DTA system.

Another disadvantage of the TG/DTA equipment is the tendency for sample temperatures to deviate from the programmed temperature over the course of thermal events. This deviation may have a noticeable influence on measurements involving the rate of weight loss for the sample under investigation.\(^9\)

It should further be noted that the DTA signal as obtained from a TG/DTA equipment is slightly different from the signal that is recorded from a conventional DTA unit. In a conventional DTA unit, differential temperature measurements are taken for a sample enclosed in a crimped crucible. For TG/DTA units, the DTA data obtained are generated from an open crucible. The event of the sample undergoing the process of sublimation is inevitable and this will therefore have a marked effect on the DTA signal. However, it is not possible to use a crimped crucible to collect TG data because the principle of thermogravimetric analysis is based on observations of mass changes while the sample is being heated.

2.4 Advantages of Simultaneous Thermogravimetry and Differential Thermal Analysis

There are several advantages that present an excellent case for advocating the use of simultaneous techniques. The obvious incentive of the time and cost efficiency of operating a simultaneous unit is perhaps the most important factor from an administrative point of view. However, there exist other technical aspects to the advantages derived from using simultaneous equipment.

If separate single techniques were used to analyze non-representative sample materials, a direct comparison of the TG and DTA curves would prove to be difficult, due to the nonuniform nature of the sample. By running a single sample of this sort of material with a simultaneous technique, the problem of analyzing nonrepresentative samples is eliminated. Some typical examples of nonuniform materials include coal, limestone and cement.

Another advantage of simultaneous techniques is that the analyst may ensure that the thermal environment and the sample temperatures are identical for the collected data sets. Hence, this technique yields data that are obtained under the same experimental conditions and the relationship between the TG and DTA traces are actual. This also obliterates the hassle of attempting to match the experimental conditions of two separate analytical units, in order to obtain comparable data.

In addition, the use of simultaneous techniques also allows for the regulation of the ambient temperature and the flow rate conditions of an experimental set-up. It is often assumed that the atmospheric environment immediately in contact with the sample for two different single techniques remains unchanged. In practice, this may differ by virtue of the discrepancies in the geometry of the sample container and the furnace enclosing the sample.

3 LINKING COMPUTER SYSTEMS WITH SIMULTANEOUS THERMOGRAVIMETRY AND DIFFERENTIAL THERMAL ANALYSIS

The tremendous influence of microcomputers on the evolution of thermal analytical techniques and applications is indisputable.\(^{10–12}\) Consequently, the computer workstation is a vital part of any thermal analysis set-up as it is responsible for a multitude of tasks. These responsibilities range from the definition and execution of the various experimental conditions for a run, data capture, the storage and retrieval of collected data, the display of acquired data sets in the right format and the provision of a suitable arena for the application of sophisticated analysis programs to the acquired data.\(^{13,14}\)

These days, commercial simultaneous instruments are often equipped with computer interfacing for thermal analysis units. A schematic representation of a thermal analysis system linked with a computer workstation is shown in Figure 4. Currently, there are numerous data analysis programs made available to an analyst. For example, there are programs that will calculate the kinetic parameters for isothermal kinetic runs at various
temperatures using raw data collected from a sample run. Obviously it is still feasible to analyze your data with the aid of a calculator or the use of spreadsheets. However it is now possible to do the same calculations in a matter of seconds.

While it is apparent that a computer workstation is a great tool to have for use with a simultaneous thermal analysis system, it would be judicious to note that the computer data, which are acquired from a unit’s temperature sensors, are not always linear. This means that the computer acquisition system should be able to accurately convert the data signal to a temperature. In most cases, an analyst will require a ‘change of scale’ potential from the equipment and a computer program which is able to record the percentage mass change against temperature. Often, a derivative plot of the collected TG data is also desirable. Most of the newer simultaneous systems have interfaced computers which are able to process the collected data in many more ways, as required by the objectives of the particular experiment.

4 EVOLVED GAS ANALYSIS AND ASSOCIATED ANALYTICAL TECHNIQUES

The success of simultaneous techniques has led to the coupling of other conventional analytical methods with a TG/DTA system. Analytical methods such as MS, FTIR spectroscopy, GC, condensation of volatiles and chemical analysis have proven to be suitable for analyzing the gaseous output of a sample as it undergoes thermal treatment in a TG/DTA system. The main goals of coupling these techniques are to enhance the specificity of a single system and to eliminate the problems that are associated with trying to compare data sets that were collected under different experimental conditions.

EGA is a technique that is rarely used alone. In most cases, it is added to an existing thermal analysis system, to enable a detailed study of the gaseous species that evolve from a sample as it undergoes thermal treatment. The basic components of an EGA system are presented in Figure 5. In order to analyze gases from solid or liquid samples, a pyrolysis unit is needed to induce the thermal breakdown of the samples into its gaseous species. A TG/DTA system is often used for this purpose. A purified carrier gas (such as helium) is then utilized to direct the evolved gas species from the sample to a detector. There are many detection methods available to analyze the gaseous samples. The analytical methods of MS, FTIR and GC will be discussed in the following sections. A brief mention of other less common detection techniques will also be presented.

It should be noted that the method of EGA is not to be confused with evolved gas detection (EGD). EGA refers to a method that involves the quantitative detection and the determination of the identity of the various gases that are given off as the sample undergoes physical and chemical changes upon heating, while EGD merely entails the detection of gases that are evolved from a sample as it is being heated.

4.1 Mass Spectrometry

MS is an analytical technique that is widely used and often associated with EGA. It is an excellent method for the detection and identification of gaseous species.
A prototype of a basic set-up of a TG/DTA/MS unit used for EGA is shown in Figure 6. The idea of the direct linkage of a thermal analyzer to the mass spectrometer has merit, as a simultaneous technique would overcome interfacing problems. However, the conditions of thermal decomposition under a controlled temperature program are rather unique and therefore the results should be viewed cautiously.

One of the earliest reports of the coupling of MS with EGA was published by Gohlke and Langer. Over the years, several designs for linking a mass spectrometer to a TG/DTA system have been established. Today, most of the modern commercial systems follow two basic designs and these are illustrated in Figures 7 and 8.

Though it is possible to purchase commercial units, it is also feasible to interface an existing thermal analyzer unit with a mass spectrometer. In the 1960s, Zitomer managed to interface a Du Pont Model 950 TG unit with a mass spectrometer in his laboratory. A schematic diagram of his apparatus is provided in Figure 9.

Before an attempt is made to couple a thermal analysis unit with a mass spectrometer, one has to consider the requirements of the equipment set-up. There should be a means of regulating the pressure of the evolved gas species from the thermal analysis unit as it is being channeled...
into the mass spectrometer. A thermal analyzer is usually operated under atmospheric pressure conditions while the gas species that are introduced to a mass spectrometer should typically be of low pressure.

Generally, the use of a capillary tube or a diaphragm is sufficient to act as an interface to cope with the primary stage of reducing the differences in pressures between both of the analytical units. In a basic system, the evolved gas is extracted from the sample chamber through a flexible heated silica-lined steel capillary. Other methods of pressure reduction include the use of jet or orifice separators.\textsuperscript{24,25} If required, a secondary pressure reduction can be achieved with the use of a molecular leak such as a silicon carbide frit.\textsuperscript{26} The purpose of these manipulations is to minimize the chance of secondary reactions and to collect the EGA data as expeditiously as possible.

4.2 Fourier Transform Infrared Spectroscopy

The coupling of FTIR spectroscopy with a thermal analysis unit to perform EGA is another well-established method for the analysis of gaseous species.\textsuperscript{27–30} The main feature of this system is the utilization of an infrared cell (set at a fixed wavelength) that is used as the detection chamber. The experimental design of this system involves channeling the gaseous products at atmospheric pressure, through a pathway of inert carrier gas and into the detection chamber. An ideal choice for the inert carrier gas would be dry nitrogen. A schematic representation of a typical system is shown in Figure 10.

There are several advantages to this method of EGA, including high specificity and the relatively fast data acquisition times. In addition, this is also an ideal technique for the analysis of samples which have proven to be difficult to study on a mass spectrometer. Some typical examples of such materials are carbon monoxide, carbon dioxide and water.

4.3 Gas Chromatography

The analytical technique of GC is not used as a detection method in an EGA system. Rather, the function of a gas chromatographic column is to separate the gaseous products evolved from a thermal analyzer before passing it on to a detector.\textsuperscript{31–33} The main purpose of using a TG/DTA/GC/MS set-up is to induce a partial separation of the evolved gaseous species before they are further analyzed. Therefore, the scheme of equipment used in such an EGA system proceeds from a thermal analyzer, followed by a GC separation column and into a detector of choice. Frequently, the detector selected for use with this system is a mass spectrometer.

5 APPLICATIONS OF SIMULTANEOUS TECHNIQUES

In 1969, an interesting application of simultaneous techniques involved the use of a system that was specifically developed to analyze the characteristics of soil found on Mars.\textsuperscript{34} The continued development and improvement of simultaneous thermal analyzers has brought forth a whole new range of applications. These applications have been used to study a vast selection of materials. In the following sections, the applications of simultaneous techniques to biological and pharmaceutical materials, organic and polymeric compounds and inorganic compounds will be stated briefly. While the various applications of simultaneous techniques mentioned here are not a comprehensive survey of all the applications in this area of thermal analysis, it is hoped that the information will challenge new and advanced analysts in exploring the uncharted territories of new applications to come.

5.1 Biological and Pharmaceutical Materials

Simultaneous techniques as applied to biological and pharmaceutical materials, have become indispensable tools to scientists in research and development laboratories. In the field of pharmaceutical studies, there are numerous applications. For example, the behavior of ibuprofen has been extensively studied with the aid of TG/DTA experiments.\textsuperscript{35,36} The melt and evaporation processes of ibuprofen are easily observed from the data acquired from the simultaneous equipment. Other experiments which have been conducted on simultaneous thermal analyzers, include the evaluation of lactose crystalline forms with TG and DSC,\textsuperscript{37} the compatibility of ascorbic acid,\textsuperscript{38} nefazodone\textsuperscript{39} and cephalexin monohydrate\textsuperscript{40} with excipients.

5.2 Inorganic Compounds

Some recent investigations of inorganic compounds with the aid of simultaneous techniques include the growth of
MgO-doped LiNbO₃ single-crystal fibers, the thermal behavior of catalysts with superacid properties, the thermal decomposition of ceric ammonium nitrate and the thermal degradation processes of Zr(SO₄)₂ · 4H₂O. As with the field of pharmaceutical studies, simultaneous techniques are frequently used to perform routine analyses for novel inorganic compounds.

5.3 Organic and Polymeric Compounds

The use of simultaneous thermal analysis methods in the investigation of organic and polymeric compounds has evolved over the years. For example, a comprehensive analysis of starch has been conducted with the use of a TG/DTA unit. Another example of recent applications in this area is the characterization of the resistance of diamond layers to oxidation on metal surfaces.

REFERENCES

Thermogravimetry (TG or TGA) is a technique in which the mass of a substance is measured as a function of temperature whilst the substance is subjected to a controlled temperature program.\(^{1,2}\) Commonly materials can be heated or cooled in the temperature range from \(-160\) to \(1600^\circ\text{C}\) at rates of fractions of a degree per minute up to \(100^\circ\text{C}\text{min}^{-1}\). Sample sizes are from 10–100 mg, although apparatus is available which can take larger sample masses. Different atmospheres can be used, from inert gases such as nitrogen, to reactive gases such as oxygen, hydrogen and vapors. The sensitivity of the apparatus is usually in the microgram range, with an accuracy of \(\pm 1\%\) and a similar level of precision. The results obtained from TG experiments are subject to a variety of experimental variables, and an understanding of the effects of these is essential to a correct interpretation of the results. TG can be used to study any physical or chemical reaction which gives a mass change, and includes absorption and desorption of gases, sublimation and vaporization, the thermal decomposition of a wide range of materials from inorganic compounds to polymers, the reaction between a gas and a solid, and solid–solid reactions. TG has also been widely used to carry out kinetic studies on solid materials, with the aim of determining the reaction model and the kinetic parameters of activation energy \((E)\) and frequency factor \((A)\). However, considerable care is required in the interpretation of the results obtained.

1 INTRODUCTION

The definition of TG as given by the International Confederation for Thermal Analysis and Calorimetry (ICTAC) is “a technique in which the mass of a substance is measured as a function of temperature whilst the substance is subjected to a controlled temperature programme”.\(^{1,2}\)

A controlled temperature program can mean:

- Heating or cooling the sample at some defined constant rate, and monitoring the mass change as a function of temperature. This is the most common mode of operation.
- Holding the sample at some constant temperature and monitoring the mass change as a function of time, called isothermal TG.
- Varying the heating rate in such a manner that the rate of mass change is constant. This mode of operation is called controlled rate thermal analysis (CRTA).\(^{3,4}\)
- Varying the heating rate continuously in order to maximize the resolution of mass changes. When no mass change is taking place, the heating rate is high, but then slows down as a mass change begins. Once
the mass loss is complete the heating rate increases again until the next mass loss. This method is called high resolution TG by some manufacturers.

- Superimposing a sinusoidal temperature program on the underlying linear heating rate. This technique is called modulated thermogrammetry (MTG or MTGA), and has been proposed as a new method for the determination of kinetic information.\(^{5}\)

Thermogravimetric data is usually presented as a plot of the mass against time or temperature (the TG curve), with the mass loss on the ordinate plotted downwards and mass gains plotted upwards (Figure 1). The TG curve can be defined in several ways. The temperature at which a change in mass is first detected is called the initial temperature \(T_i\), or onset temperature or procedural decomposition temperature. The initial temperature is not sufficiently well defined to use as a satisfactory reference point, since its detection is dependent on factors such as the sensitivity of the TG apparatus, and the rate at which the initial reaction occurs. If the initial rate of mass loss is very slow, then the determination of \(T_i\) can be uncertain.

A more satisfactory approach is to use the extrapolated onset temperature, \(T_o\), which provides consistent values (Figure 1). If, however, the decomposition extends over a wide temperature range and only becomes rapid in its final stages, the extrapolated onset temperature will differ considerably from the onset temperature. For this kind of reaction, it is more satisfactory to measure the temperature at which a fractional weight loss, \(\alpha\), has occurred \((T_o)\) (Figure 1). Clearly the temperature \(T_{0.05}\) is close to that at the start of the reaction and \(T_{0.5}\) is the mid-point of the reaction. In order to define the complete range of reaction, two further temperatures \(T_o\) and \(T_f\) may be identified as shown in Figure 1.

Alternatively the mass change can be presented as the derivative thermogravimetric curve which is a plot of the rate of change of mass with respect to time or temperature against time or temperature (Figure 2). Differential thermogravimetry (DTG) mass losses should also be plotted downwards and gains upwards. When a horizontal plateau is obtained in a TG curve, a minimum at which \(dm/dt = 0\) is observed in the DTG curve. A maximum in the DTG curve corresponds to a point of inflection in the TG curve at which mass is lost (or gained) most rapidly. Minima can also occur in a DTG curve at which \(dm/dt > 0\), corresponding also to a point of inflection in the TG curve, rather than to a horizontal plateau.

The DTG curve is particularly useful in displaying subtle changes in mass which are not easily discernible on the TG curve. The DTG curve also allows the ready determination of the temperature at which the rate of mass loss is a maximum \((T_p)\), and this provides an additional characteristic temperature to those already described in Figure 1.

The DTG curve can assist the operator to be aware of overlapping reactions. A single reaction which occurs over a small temperature range gives rise to a single well-defined peak (Figure 3a). Two reactions which are partially overlapping result in two peaks in which the minimum does not return to the baseline (Figure 3b). If a slow reaction occurs over a wide temperature range, followed by a fast reaction, then the former gives a small broad initial DTG peak followed by a well-defined one (Figure 3c). Minor reactions which occur during or near a major reaction can frequently be identified by the appearance of a shoulder or separate small peak in the DTG curve (Figure 3d). Finally, slow reactions which occur over wide temperature ranges, in which other reactions happen, produce gradient changes in the DTG curve. Because the subtleties of the TG curve are visually emphasized in the DTG curve, the latter are frequently recorded as a ‘fingerprint’ of a new, unknown or standard material.
Since the area under the DTG peak is directly proportional to the mass change, the area or even the peak height can be measured for quantitative purposes. The advantage of DTG in this application is that when no weight change is taking place, the baseline returns to the zero position and so only a simple baseline construction is required. The value of TG is considerably enhanced when the product at the end of each mass change is characterized. A range of qualitative and quantitative analytical methods are available which can be performed on a few milligrams of the sample. This kind of information can be used to write the chemical reaction associated with the mass loss. Information on reaction mechanisms can be obtained from techniques such as scanning electron microscopy (SEM).

There is an extensive literature associated with thermal methods of analysis, which includes two journals dedicated to the techniques, the *Journal of Thermal Analysis* and *Thermochimica Acta*. There are also several standard texts available which contain sections on TG, as well as review articles in texts.\(^{6–13}\)

2 COMPONENTS OF THERMOGRAVIMETRY APPARATUS

All TG apparatus consist of the essential components of a balance, a sample chamber, a furnace with associated temperature programmer, a method of measuring sample temperature, and a means of acquiring and outputting the data collected. TG systems are available from a number of commercial manufacturers.

2.1 The Balance and Methods of Calibration

The most commonly used balance to follow the mass change in TG apparatus is the null deflection microbalance, in which the position of the beam is monitored. When a mass change occurs, a servo motor maintains the beam in its original position, and the restoring force is proportional to the mass change. The null deflection balance has advantages in that the sample stays in a constant position in the furnace. Sample masses of typically 10–20 mg are sufficient to be able to detect mass changes accurately and reliably. TG apparatus capable of taking larger samples, in the gram range, are also available, although tend to be used for specialist applications.

There are a number of factors which can affect the accuracy and precision of mass measurement and these are discussed in detail in Dunn and Sharp.\(^{11}\) For most usage, that is where the mass loss is above 1% of the sample mass, the errors that arise in microbalance TG apparatus can be ignored. The extent of typical errors can be assessed by following a simple protocol:

- The microbalance is calibrated with standard weights to check that the balance is operating within specification (this procedure should be done at regular intervals, say once a month). Standardized masses are often provided as part of the accessories when a commercial thermobalance is purchased, or sets of such mass calibrants can be obtained from organizations such as ICTAC, the National Physics Laboratory (NPL), or NIST (National Institute for Science and Technology).
- A blank experiment is carried out with empty sample pans, which will enable the amount of noise and
base line stability (including balance drift) to be determined.

- A further experiment is carried out with a typical sample size of an inert material such as calcined alumina, which will enable the buoyancy effect to be established. The buoyancy effect produces an apparent mass gain which increases with increasing temperature and with increasing sample mass.

- Experiments are carried out with a standard material which decomposes to a known product, and the observed mass loss is compared with that expected theoretically. Multiple experiments on the same sample will give statistical information on the accuracy and reproducibility of the results. If the difference is within the acceptable error, experiments with unknown samples can then be carried out under the same experimental conditions.

2.2 The Sample Chamber and Atmosphere Control

The sample chamber usually consists of a glass envelope which encloses the balance, partly to protect the balance against corrosion or damage, but also to enable experiments to be carried out in a controlled atmosphere. One simple way to protect the balance mechanism from corrosion is to flow an inert gas over the balance first and then over the sample. A reactive gas, such as oxygen, can be introduced as a second gas stream nearer to the sample, but again arranged in such a way that gaseous products are swept away from the balance mechanism. A typical example is the reaction between chlorine and lead sulfate.\textsuperscript{14} Other configurations are illustrated in Dunn and Sharp.\textsuperscript{11} Gas flow rates are measured with a rotameter.

Pahlke and Gast\textsuperscript{15} have overcome the problem of corrosive gases attacking the microbalance by designing a system in which the balance and sample chambers are completely separated. The mass change is monitored by a magnetic link. The sample chamber is often sufficiently sealed to permit work under vacuum down to 1 torr (1 torr = 133 Pa), and many thermobalances can operate down to $10^{-3}$ torr ($= 0.133$ Pa), although it is not usual to find instruments fitted with a means of monitoring the vacuum level. TG apparatus capable of operating at high pressures is available.

2.3 The Furnace

A furnace provides the thermal environment for the sample. The temperature ranges for commercially available instruments given in the manufacturers literature tend to be for the basic model, which operates typically in the temperature range ambient to 1000 °C, but other models may operate from $-196$ °C to 500 °C, or ambient to 2400 °C, with other ranges between.

One of the requirements of a furnace is that there should be a region, called the hot zone, within which the temperature is constant over a finite distance. The importance of this is that the sample should always be in the hot zone, so that all of the sample is at the same temperature. This is one of the reasons why it is advantageous to use a null deflection balance, as the sample is always in the same position in the furnace.

There are three main arrangements of the furnace relative to the weighing arm of the balance. Lateral loading is a horizontal arrangement, in which the balance arm extends horizontally into a furnace aligned horizontally. Two vertical arrangements are possible, one with the balance above the furnace with the sample suspended from the balance arm (bottom loading); and the other with the balance below the furnace, and the sample resting on a flat platform supported by a solid ceramic rod rising from the balance arm (top loading).

2.4 Measurement of Temperature and Methods of Calibration

The sample temperature is measured by a thermocouple ideally in contact with the sample, but in practice this is difficult and the best compromise situation is one in which the thermocouple is placed at a fixed distance from the sample. Again this is an advantage of the null deflection balance since the position of the sample is relatively fixed. Even so, the accurate measurement of temperature in TG experiments is difficult. Some typical configurations of thermocouples with respect to the sample are shown in Figure 4. The thermocouples are often made of platinum/rhodium and their alloys.

One of the better calibration methods involves the use of the Curie point transition in metal samples. In this procedure, a ferromagnetic material is placed in the sample crucible as the test specimen and a magnet is located above or below the crucible which creates a magnetic flux aligned to the gravitational field. When the material is heated at a particular temperature

![Figure 4](image-url)
the ferromagnetic material becomes paramagnetic. The temperature at which the magnetic properties change is defined as the Curie temperature. At the Curie point a significant apparent mass loss in the specimen occurs.\(^{16}\) Five metals have been certified as ICTAC certified reference materials for TG, GM761, as shown in Table 1.\(^{17}\) The materials cover the temperature range 200–800 °C.

More reproducible and precise results for determining transition temperature can be achieved using simultaneous thermomagnetometry/differential thermomagnetometry/differential thermal analysis (TM/DTM/DTA).\(^{18}\) The results from five different laboratories, based on DTM, showed that a very high degree of reproducibility between the laboratories was obtained with a standard deviation 2σ value of ±0.2 °C. The potential of nickel–cobalt and nickel–copper alloys, which give magnetic transitions from 1100 °C to below room temperature, have also been investigated.\(^{19}\)

The obvious advantage of the Curie point method is that the ferromagnetic material calibrates temperature directly at the sample position and the thermobalance can be calibrated under the same conditions as used with a sample. The magnetic transitions are reversible, so that the calibrant can be encapsulated to protect it against oxidation and used repeatedly for calibration purposes.

If the sample is visible when placed in the TG sample pan, then the melting of a pure compound can be used for calibration purposes. The method is to heat the calibrant to just below its melting point and then increase the temperature in small increments of say one degree until the calibrant just melts. Sets of melting calibration standards are available from organizations such as NIST, covering the temperature range ambient to 1000 °C. The obvious disadvantage of this method is that the calibrant needs to be visible, and the calibration is carried out under near isothermal conditions instead of the rising temperature program most commonly used for experimental purposes.

### 2.5 The Temperature Programmer

The temperature programmer is the device which enables the sample to be heated at a linear and reproducible set of heating or cooling rates. In the isothermal mode of operation, it should be able to hold a fixed temperature to within ±1 °C. The thermocouple output is usually fed to a microprocessor containing tabulated data on thermocouple readings, so that the conversion to temperature is made by direct comparison.

### 2.6 Data Acquisition and Manipulation

Data acquisition and manipulation is carried out by conversion of the millivolt output from both the balance and the sample thermocouple via an interface, and the digitized data stored on a microprocessor. Once the data has been acquired it can be manipulated in various ways, and some common examples are given as follows:

- rescaling of either the mass or temperature scales, so that the data can be displayed to best advantage;
- differentiation of the mass change to give the DTG curve;
- produce a report quality output of fully labeled TG/DTG curves with the various onset and offset temperatures identified, and mass losses expressed in various units including percentage values. Labels identifying the sample, operator, and experimental conditions used can be added;
- carry out various calculations including a kinetic analysis of the data. This aspect will be discussed in more detail in section 5.7.

The other role of the computer is as a control system, which enables a particular protocol to be established to carry out a repetitive test procedure. Heating and cooling rates can be varied at will, and over a range from fractions of a degree per minute to the maximum that the system will allow. This control function can be extended to switching on or off valves so that different atmospheres can be admitted to the TG equipment.

The availability of automatic sample loaders which allow multiple samples to be presented to the TG apparatus has been the most recent development.

### 3 EFFECT OF EXPERIMENTAL VARIABLES

The shape of the TG curve is dependent on the properties of the sample and the experimental variables chosen. These parameters include sample preparation, sample mass, sample containers, heating rate, and the atmosphere surrounding the sample. Most of the effects observed are
related to mass and heat transfer between the sample and the TG apparatus, which result in shifts in the temperature range over which the mass change occurs. In some instances the change in conditions will produce a change in the reaction mechanism and produce a TG curve which is quite different to that obtained under other conditions. An obvious example is when the atmosphere is changed from an inert gas to a reactive one, although sometimes a change in heating rate can bring about a change in the reactions that the material undergoes. If reactive materials (such as organic compounds, coals, and sulfides) are subjected to vigorous oxidizing conditions, the material may ignite and the excess heat generated in the reaction may heat the sample above that defined by the temperature programmer. This is evident as a distortion on the heating rate record. Hence it is necessary to know about the effects of these variables in order to interpret the results correctly and also to compare results with those published in the literature.

3.1 Sample Preparation

Most solid samples require some form of sample preparation prior to performing the experiment. Since TG apparatus based on microbalances require sample sizes in the milligram range, it is essential to grind the sample to a small enough particle size, typically less than 100 µm, to enable a representative sample to be taken. Particle size affects the TG record in two ways. First, smaller particles will heat more rapidly than larger ones, and second the rate of reaction becomes greater as the particle size decreases. In general, therefore, the smaller the particle size of the sample, the lower the temperature at the start and the completion of the reaction, which is manifest as a shift in the mass change along the temperature axis but with the general shape of the TG being retained. Figure 5 shows the TG curves for four different sample preparations. A thin film of a fine powder gives the lowest commencing and finishing temperature, followed by a thick film of a fine powder, then a coarse powder and finally at the highest temperatures a pellet of the material.

Some materials, when heated, can be ejected from the sample pan and give a mass loss which may be incorrectly attributed to a chemical reaction rather than a physical loss. Samples which are in this category are those which decrepitate, or which dehydrate with subsequent dissolution of the solid in the water which boils with frothing. Organic samples, if oxidized vigorously, may ignite and the solid material be carried away as a fine ash. Such problems can be solved by use of a cover on the sample pan.

3.2 Sample Mass

The sample mass is important for a number of reasons. For decomposition reactions, the sample mass affects the rate of diffusion of reaction products away from the sample. In general a larger sample mass will not significantly affect the onset temperature of reaction, but \( T_p \) and final temperatures will tend to be at higher values. Figure 6 shows the DTG curves for different masses of calcium carbonate.\(^{20} \) The \( T_{0.1} \) values change by 59 °C, the \( T_p \)
values by about 80 °C, and the $T_{0.90}$ values by 97 °C, as the sample mass changes from 50–300 mg. This is similar in the reaction between a sample and an introduced reactive gas. The larger the sample the larger will be the temperature interval over which the reaction occurs.

Another effect that needs consideration is the temperature gradients which exist within the sample. Temperature gradients are found in any procedure in which a dynamic heating or cooling rate is used. There is a temperature gradient between the furnace and the sample, as it takes a finite time for heat transfer to take place across the air gap between the furnace and the sample. Only under isothermal conditions will the sample and furnace temperatures be the same. At a constant heating rate this temperature gradient or, as it is more commonly known, the thermal lag, is approximately constant. The thermal lag increases as the heating or cooling rate increases, and also increases as the mass of the sample increases. The various heats of reaction that occur will contribute to the magnitude of the effect as well. Exothermic reactions will tend to heat the sample and reduce the thermal lag, whereas endothermic reactions will tend to cool the sample and increase the thermal lag.

There are also temperature gradients within the sample. Heat diffusion will be dependent on the thermal conductivity of the sample, so that heat gradients in metals will tend to be lower than minerals or polymers. If a large sample of a poorly conducting material is heated then large temperature gradients can be expected and so the rate of reaction will be faster at the exterior of the sample because it is at a higher temperature than the interior. This will cause the reaction to occur over a greater temperature range relative to a smaller sample mass or one with a better thermal conductivity.

These problems are in general minimized in the microbalance-based TG apparatus, since sample sizes are small and heat and mass transfer tend to be rapid. Nevertheless, it is sometimes necessary or advantageous to use large samples (300–1000 mg range) and the associated effects need to be considered.

To reduce heat and mass transport effects, small samples spread as a fine layer are preferred. This ensures that gaseous products are dispersed quickly, thermal gradients in the sample are small, and the reaction between solid and introduced reactive gas is rapid.

### 3.3 Sample Containers

Both the geometry of the sample container and the material from which it is made can influence the shape of a TG curve. The geometric effect is again related to gas diffusion to and from the sample. Deep narrow necked crucibles will reduce the rate of gas diffusion and tend to make the reaction take place over a larger temperature range relative to a shallow open pan. Sometimes these effects are quite marked and it has been demonstrated that the rate of oxidation of pyrite decreases by about one half as the wall height of the sample pan changes from 2–4 mm.

In certain situations it is advantageous to inhibit gas diffusion deliberately, by use of a lid with either a partial or complete seal, or of special design, for example the “labyrinth” crucible of Paulik et al. The partial pressure of the gaseous product reaches atmospheric pressure and remains constant until the end of the process, so leading to the technique being named quasi-isobaric. Lids are of value in preventing sample loss, as well as holding the sample firmly in place.

Crucibles are usually fabricated from either metal (often platinum) or ceramic (porcelain, alumina or quartz) and their thermal conductivity varies accordingly. Care must be taken to avoid the possibility of reaction between the sample and its container, which may result in the corrosion of the crucible and/or a change in the rate of reaction if some catalytic effect is present.

### 3.4 Heating Rate

The heating rate will affect the temperature range over which a TG curve is observed. As the heating rate increases, the mass loss is usually displaced to a higher temperature range and occurs over a larger temperature range. Faster heating rates may also cause a loss of resolution when two reactions occur in similar temperature ranges and the two mass losses merge. Figure 7 shows the DTG curves for 20 mg of a 50:50 mixture of inorganic bicarbonates heated at 1 and 20 °C min$^{-1}$, respectively, in nitrogen.

![Figure 7](image_url)
bicarbonates decompose on heating with the evolution of carbon dioxide. At the slower heating rate, the reaction commences at a $T_e$ value of $88\,^\circ C$, the $T_p$ values for the first and second reactions are $127\,^\circ C$ and $154\,^\circ C$, respectively, and the $T_o$ value is $172\,^\circ C$. At the faster heating rate the four values shift to 115, 172, 209 and 233 $^\circ C$.

Changes in heating rate sometimes leads to a change in mechanism which produces a significantly different TG curve.

### 3.5 The Atmosphere

The atmosphere causes two major effects. First, the presence in the atmosphere of an appreciable partial pressure of a volatile product will suppress a reversible reaction and shift the decomposition temperature to a higher value. This effect can be achieved by having a large sample with a lid, or introducing the volatile component into the inlet of the gas stream. When the atmosphere within the crucible is the result of the decomposition of the reactant, the atmosphere is described as self-generated.\(^{25}\) The second major effect is the interaction of a reactive gas with the sample, which will change the course of the reaction. Under an inert atmosphere, organic compounds will degrade by pyrolytic decomposition, whereas in an oxidizing atmosphere oxidative decomposition obviously takes place. Hydrogen can be used to study reductive processes, although great care has to be taken to remove all oxygen from the system before carrying out the reaction. Other gases frequently studied are SO$_2$ and halogens.

A more minor effect is the due to the differences in the thermal conductivity of gases. If two inert gases with differing thermal conductivities are used to conduct two experiments then there will be a difference in the TG curves. This is because the gas with higher conductivity will in general conduct heat to and from the sample at a greater rate than the one with lower thermal conductivity. This will not much affect the onset temperature of reaction, but the $T_p$ and $T_t$ values will be lower for the gas with higher conductivity. This is illustrated in Figure 8, which shows the DTG curves for the same bicarbonate mixture referred to in the previous example.\(^{24}\) In both experiments the sample mass is 10 mg, and the heating rate is $10\,^\circ C\,\text{min}^{-1}$, but the purge gases are helium and nitrogen. Helium, with a higher conductivity than nitrogen, causes the mass losses to occur at lower temperatures relative to nitrogen. The effect is not large, with the $T_p$ values for the second reaction differing by $24\,^\circ C$ between the two different gases.

### 3.6 Optimizing Thermogravimetry Results

It should be evident from the foregoing comments and examples that the conditions required to minimize the effects of heat and mass transfer as well as decreasing the possibility of change of reaction sequence are to have:
- a small sample (10–20 mg)
- finely ground material (<100µm)
- a slow heating rate (10–20 $^\circ C\,\text{min}^{-1}$)
- a thin film spread evenly in a flat open pan made of an inert material.

Such conditions will allow maximum resolution of close reactions and give well-defined mass losses over relatively narrow temperature ranges. However, it should be emphasized that when dealing with a sample of unknown properties that it is advisable to use a range of different conditions to ensure that the sample behaves in a similar manner. Thus if the only effect noticed on increasing the heating rate is a modest shift to higher temperatures of the mass losses, then it can be assumed that the reaction sequence is the same and the increased temperature is just the result of an increase in the thermal lag of the sample. Any marked difference in the temperature at which mass losses occur, or the number of mass losses, may indicate a change in reaction sequence.

In some circumstances it is not possible to use the above conditions, for example when measuring small mass changes which may require large samples to give accurate mass values, or when doing combined TG–evolved gas analysis experiments where the evolved gas concentration needs to be increased in order to be detected.

4 REPORTING THERMAL ANALYSIS RESULTS

It has been stressed that TG results are very dependent on the sample properties and the experimental conditions used. In order to facilitate a comparison of results obtained by different workers, it follows that these various parameters, such as particle size, heating rate and so on, should be reported.

The existing recommendations for reporting thermal methods of analysis were developed by the Standardization Committee of ICTAC in the late 1960s and early 1970s, and are also in various standards such as American Standard Test Methods, ASTM E472-86. The recommendations are presently in revision to take into account current practice. The draft document is reproduced below, although it has not at the time of writing been officially ratified by the Council of the ICTAC. There has been some change of emphasis in the new draft and more emphasis has been placed on accurate characterization of the sample, as well as in giving details on the way in which the computer acquires and processes data. The section relating to the experimental conditions is largely unchanged. This paper does not address safety problems associated with the use of the related materials or equipment. It is the responsibility of the user to establish the appropriate safety standards and work within the validity of the given safety laws.

Accompanying each thermal analysis record should be information about the properties of substances, experimental conditions and data acquisition and manipulation methods.

4.1 Properties of Substances

1. All substances (sample, reference, diluent) should be identified by a definitive name, an empirical formula, or equivalent compositional information.
2. A statement of the source of all substances, details of their histories, pretreatments, physical properties, and chemical purities, as far as they are known should be given.
   (a) “Histories” includes method of acquisition or manufacture of the sample (how it was isolated or made, manufacturing conditions, e.g. grinding, sizing, etc.), previous thermal and mechanical treatments (e.g. repeated grinding, sintering, all experimental conditions), surface modification, and any other physical or chemical treatment.
   (b) “Pretreatments” includes preparation of the sample prior to the thermal analysis experiment.
   (c) “Physical properties” includes particle size, surface area, porosity.
   (d) “Chemical purities” includes elemental analysis, phase composition, and chemical homogeneity of sample.

4.2 Experimental Conditions

1. A clear statement should be given of the temperature environment of the sample during measurement or reaction, including initial temperature, final temperature, rate of temperature change if linear, or details if not linear.
2. The sample atmosphere should be identified by pressure, composition, and purity: whether the atmosphere is static, self generated or dynamic through or over the sample. Where applicable, the ambient atmospheric pressure and humidity should be specified. If the pressure is other than atmospheric, full details of the method of control should be given.
3. A statement of the dimensions, geometry and materials of the sample holder, and the method of loading the sample where applicable should be given.
4. The abscissa scale should be identified in terms of time or temperature at a specified location. Time or temperature should be plotted to increase from right to left.
5. A statement of the methods used to identify intermediate or final products should be provided.
6. Faithful reproductions of all original records should be provided.
7. Wherever possible, each thermal event should be identified and supplementary supporting evidence stated.
8. Sample mass and dilution of sample should be stated.
9. The apparatus should be identified by the provision of the manufacturer’s name and model number. More detail should be provided if significant modifications to the standard commercial model have been made, or if the apparatus is not commercially available.

4.3 Data Acquisition and Manipulation Methods

1. The instrument manufacturers software version should be identified, or details of any self-developed versions given.
2. Equations used to process data, or reference to suitable literature should be given.
3. The frequency of sampling, filtering and averaging of the signal should be given.
4. An indication should be provided of the smoothing and signal conditioning used to convert analog to digital signals, or reference to suitable literature. Similar information for subsequent processing of the digital data is also needed.

The following information is required specifically for TG.

- The ordinate scale should indicate the mass scale. Mass loss should be plotted as a downward trend and deviations from this practice should be clearly marked. Additional scales (for example, fractional decomposition, molecular composition) may be used for the ordinate where desired.
- The method used for the calibration of the temperature and mass should be indicated.
- If DTG is employed, the method of obtaining the derivative should be indicated and the units of the ordinate specified.

5 APPLICATIONS

TG can be used in any application in which there is a change in mass. Table 2 gives the range of physical and chemical reactions that have been studied. The information gained from TG experiments can be considerably enhanced by the characterization of intermediate products, so that the proposed reaction scheme is a confirmed one rather than speculation. If the TG experiment is stopped after a mass change and the sample cooled down to ambient temperature in an inert atmosphere, the product can be isolated and characterized. An X-ray diffraction (XRD) pattern, for example, may permit the determination of phases present. Fourier transform infrared spectroscopy (FTIR), electron probe microanalysis (EPMA), and SEM are other techniques that can assist in the elucidation of a reaction scheme. What is more, these methods can be carried out on a few milligrams of sample and can be used to supply both qualitative and quantitative information. Examples of the application of these techniques to TG studies will be given in the following sections.

5.1 Adsorption and Desorption Reactions

Any solid material which adsorbs gases, such as catalytic materials and air cleaners, can have their sorptive and desorptive properties studied by TG. The gain in mass at any given temperature is related to the number of occupied sites. Usually a steady mass gain is observed up to a certain temperature and then a limiting diffusion rate gives rise to a plateau in the TG curve.

During a heterogeneous catalytic reaction, gaseous molecules are adsorbed onto the surface of the active catalytic sites. Since the activity of the catalyst is dependent on the number of available adsorption sites, which in turn is related to the surface area of the catalyst material, it is of some importance to be able to measure the latter. TG has the major advantage of continuously monitoring the weight gain which results from gas adsorption and this gives information on the rate of gas uptake as well as the attainment of equilibrium conditions. Providing there is monolayer coverage and the number of molecules of gas adsorbed per unit of catalyst is known, from the gain in mass at a specific temperature it is possible to calculate the specific surface area of the catalyst material.

The total area of the catalyst material, i.e. catalyst plus support medium, is usually measured by the physical adsorption of an inert gas typically at subambient temperatures using a vacuum microbalance. This topic has been discussed in more detail by Keattch and Dollimore. Measurement of the surface area of the active catalyst alone requires gases which are chemisorbed by the catalyst and hydrogen and carbon monoxide are frequently used in this role. Some knowledge of the stoichiometry of the surface reaction is required.

It is sometimes useful to monitor the adsorption behavior of the catalyst in the temperature range at which reaction occurs. To do this, the reaction gas mixture can be passed over the catalyst at specific temperatures and the weight changes followed until equilibrium is achieved. A rapid weight loss can result if the surface area of the metal are reduced by sintering, or if the decomposition temperatures of catalyst materials are exceeded.

Desorption isotherms can be monitored by heating up the solid with adsorbed material and following the mass loss. The vacuum desorption behavior of methanol adsorbed onto a zeolite catalyst between 47–227 °C is
a typical example. Approximately 40% of the methanol remained adsorbed, which was explained by pore filling. TG has been used to investigate the regeneration of materials which are used as adsorbing agents, which may involve adsorption from the gas or liquid phases.\(^{(32-34)}\)

In the gold processing industry, for example, activated carbon is used to adsorb a gold cyanide complex. Unfortunately, the carbon is not very specific in its adsorption characteristics and becomes considerably fouled by the adsorption of inorganic and organic species, which reduces its gold adsorption activity. The fouled carbon is acid washed to remove inorganic materials and then thermally regenerated by heating to 650°C for up to 30 min in steam. During this process, any organic compounds are likely to be decomposed. TG, especially when coupled with evolved gas analysis equipment such as FTIR and mass spectrometry (MS), provides a powerful tool for assessing the temperatures of decomposition of the adsorbed organic compounds, their identification, and any possible hazards associated with the evolved gases.

One reagent which is known to adsorb strongly onto activated carbon is sodium ethyl xanthate (SEX), which is used as a flotation reagent in the gold processing circuit. The thermal decomposition of SEX in a nitrogen atmosphere was studied by coupled thermogravimetry/Fourier transform infrared spectroscopy (TG/FTIR), and by pyrolysis/gas chromatography/mass spectrometry (py/GC/MS). The TG curve exhibited two discrete mass losses of 41% and 19%, respectively, in the temperature ranges 190–220°C and 220–320°C (Figure 9a).\(^{(33,34)}\) The major evolved gases resulting from the first mass loss were carbonyl sulfide, ethanol, ethanethiol, carbon disulfide, diethyl sulfide, diethyl carbonate, and diethyl disulfide. The gases identified as a result of the second mass loss were carbonyl sulfide, ethanethiol, and carbon disulfide. Hydrogen sulfide was detected in both mass losses by py/GC/MS, but not detected by FTIR. The solid residue was sodium hydrogen sulfide.

SEX was adsorbed onto activated carbon and heated in nitrogen. Two discrete mass losses were still observed, but in the temperature ranges 100–230°C and 200–340°C (Figure 9b). Carbonyl sulfide and carbon disulfide were now the dominant gases evolved in each of the mass losses and the other gaseous products were relatively minor. Hence adsorbing the SEX onto carbon changed the temperature of decomposition as well as affecting the reaction sequence.\(^{(33,34)}\) Samples of activated carbon were obtained from operating gold plants and heated in the TG/FTIR system. Carbonyl sulfide and carbonyl disulfide were detected in some of the samples, indicating the presence of adsorbed SEX.

\[ p = \frac{\Delta m}{\Delta t q} \left(\frac{2\pi RT}{M}\right)^{1/2} \]

where \(p\) = vapor pressure in dyne cm\(^{-2}\), \(q\) is the orifice area in cm\(^2\), \(\Delta m/\Delta t\) the rate of weight loss in g s\(^{-1}\), \(T\) is the temperature in K, and \(M\) is the molecular weight of the specimen. If the data fits the Clausius–Clapeyron relationship then the heat of sublimation (or if above the melting point, the heat of vaporization) can be determined.
Another method has used the Langmuir method based on the rate of escape of molecules from a surface under vacuum conditions to determine heats of sublimation. According to the Langmuir method, the rate of sublimation per unit area of substance is related to the vapor pressure by Equation (2):

$$\frac{dn}{dt} = \frac{M^{1/2}p}{[2\pi RT]^{1/2}}$$  \hspace{1cm} (2)

By choosing temperatures where the rate of weight loss was low and the overall loss was kept under 2%, good straight line Clausius–Clapeyron plots were given with slopes corresponding to the heats of sublimation reproducible to approximately 5%. Reasonable agreement was obtained with literature values for a number of the compounds studied. In addition, the value obtained for benzoic acid agreed with that obtained by Wiedemann by the Knudsen method (38) in a similar temperature range, to better than 3%.

TG can be a useful technique to check on spurious results in DTA or differential scanning calorimetry (DSC). The measurement of the enthalpy of melting of volatile materials requires the sample to be hermetically sealed into a sample pan especially where repeat determinations are to be made. TG provides the ability to check if significant volatilization occurs in the vicinity of the melting point using an open sample crucible and to investigate the integrity of the seal in an enclosed pan.

### 5.3 Thermal Decomposition and Thermal Stability

TG can be used to define various properties of a thermal decomposition reaction, as illustrated in Figure 1, and includes the extrapolated onset and offset temperatures. There is nothing absolute about these values, however, and they are all dependent on the experimental conditions used. The general application of thermal decomposition reactions is to determine the products of the reaction and so be able to write a reaction scheme. This task may be aided by an evolved gas analysis. Many compounds undergo a series of sequential decomposition reactions with increasing temperature, so that the appearance of a plateau after the first mass loss does not mean that the product at that temperature will not undergo further reaction at higher temperatures. The thermal decomposition of a wide range of materials has been studied and includes inorganic compounds, coordination compounds, polymers, natural products such as woods and wool, superconductors, cements and minerals.

An example of a thermal decomposition reaction for a coordination compound illustrates some of the points made above. $[\text{Ni(β-picoline)}_4(\text{SCN})_2]^{40,41}$ is a coordination compound which decomposes by loss of the relatively weakly bound picoline ligand. As the conditions are varied, the number of ligands lost vary, as does the temperature at which the decomposition occurs (see Table 3). In nitrogen at a moderate heating rate two ligands are lost commencing at 125°C, followed by two further losses at 190°C and 200°C, respectively. If the ligand atmosphere is inhibited from diffusion away from the sample by putting a lid on the sample crucible, the ligands are lost in a 1:2:1 ratio and the decomposition temperatures shift to higher values. In a vacuum all four ligands are lost in a single step and the decomposition temperature becomes 30°C.

TG is a technique which is particularly applicable as a rapid means of comparing the relative thermal stability of a range of materials. After the loss of volatiles such as solvents and other small molecules, the first significant mass loss is taken as the end of the thermal stability region. Heating the materials under the same experimental conditions will allow the decomposition temperature ($T_e$) or the temperature at which a chosen fraction has reacted ($T_o$) to be determined and used to place the materials in order of rank.

However, it must be emphasized that the decomposition temperature (or $T_o$) does not represent the upper limit of usefulness, as considerable decomposition can occur at lower temperatures albeit at a slower rate. Isothermal TG tests, although requiring more time, give more useful information on thermal stability. The material is heated rapidly to a preselected temperature and the mass loss followed as a function of time. Several temperatures are examined in separate experiments, thus generating a family of curves. A typical set of curves is shown in Figure 10. The material could be used quite successfully below 300°C, but at 400°C massive degradation had

5.4 Gas–Solid Reactions

One of the major uses of TG has been to study the reaction between a sample and a reactive gas. The most widely used atmospheres have been those of air and oxygen to study oxidation reactions, but if gas flows are arranged so that the balance mechanism is protected (see section 2.2) then corrosive gases e.g. chlorine, or reductive gases, e.g. hydrogen can be used. Vapors can also be introduced into the sample chamber, both under high or low pressures. In some cases, TG experiments have been carried out as the precursor to pilot-scale studies. The advantages of using TG in this role is that many experiments can be carried out rapidly and cheaply, experimental parameters can be carefully controlled, and the major factors affecting the reaction be identified. This then enables the pilot-scale study, which is a much more expensive operation to run, to focus on the important parameters and spend less time on the less significant ones. The oxidation of metal sulfides provides some typical examples of a range of reactions which cause mass and energy changes, and which can therefore be studied by thermal methods of analysis.

5.4.1 Direct Formation of Oxide

The formation of oxide can be expressed in general as Equation (3):

\[ 2\text{MS}_{(s)} + 3\text{O}_2(g) \rightarrow 2\text{MO}_{(s)} + 2\text{SO}_2(g) \]  

\[ (3) \]

The conversion of sulfide to oxide produces a mass loss coincident with an exothermic event.

5.4.2 Formation of Sulfate

The formation of sulfate usually takes place in the same temperature range as the formation of oxide and suggests that the sulfate is formed from the reaction scheme depicted by Equations (4–7):

\[ \text{MS}_{(s)} + 1.5\text{O}_2(g) \rightarrow \text{MO}_{(s)} + \text{SO}_2(g) \]  

\[ (4) \]

\[ \text{SO}_2(g) + 0.5\text{O}_2(g) \rightarrow \text{SO}_3(g) \]  

\[ (5) \]

\[ \text{MO}_{(s)} + \text{SO}_2(g) \rightarrow \text{MSO}_4_{(s)} \]  

\[ (6) \]

\[ \text{MS}_{(s)} + 4\text{SO}_2(g) \rightarrow 2\text{MSO}_4_{(s)} + 2\text{SO}_2(g) \]  

\[ (7) \]

The observed mass change is dependent on the relative rates of formation of the sulfate and oxide. Usually the first sign of reaction is a mass gain, as observed for FeS and NiS.

The formation of sulfates can be affected by several factors:

- Sulfate formation will tend to increase as particle size decreases.
- Heating rate: sulfate formation is encouraged by slow heating rates.
- Sample holder geometry: sulfate formation is enhanced in a shallow open sample holder, which allows good interchange between the incoming oxidizing gas and the outgoing sulfur dioxide product.
- Sample holder material: the formation of SO₃ is encouraged by the presence of catalytic material and hence the extent of sulfation increases. The catalytic influence of a platinum sample holder on sulfate formation is well known.
- Mass size: increasing the mass size inhibits gas diffusion, and so inhibits formation of sulfate.\(^{(50)}\)

The formation of sulfate and oxide layers can inhibit oxygen diffusion into the unreacted core of the particle. During the oxidation of chalcocite (Cu\(_2\)S), the first major mass gain is due to the simultaneous oxidation of the sulfide and formation of sulfate, but then the reaction starts to slow down and the TG curve starts to flatten off.\(^{(51)}\) At 510 °C a second major mass gain commences. It could be interpreted that these were two separate reactions. Investigation using techniques such as SEM and hot stage microscopy revealed that a thick oxide/sulfate layer had formed around the particle and arrested further oxidation. At 510 °C, however, melting occurred through reaction between Cu\(_2\)S and CuSO\(_4\), the protective film was destroyed and so further oxidation and sulfation could occur.

The determination of the above mechanisms could not have been made without the use of complementary techniques XRD, SEM, EPMA, chemical analysis, and FTIR spectroscopy to characterize the intermediate products. If the technique is quantitative then the appearance and disappearance of a particular phase can be followed as a function of temperature. Quantitative XRD can be carried out with small sample masses in the milligram range, which makes it applicable to thermal analysis studies. By using ratios of several interference-free peaks in the XRD record of the partially reacted mineral against some internal standard, it is possible to produce several results from one experiment which can be averaged to produce a reasonably reliable value. The XRD analysis of the Cu\(_2\)O content of partially oxidized chalcocite as a function of temperature is given in Table 4.\(^{(52)}\) It is evident that wide variation can occur between individual values, but the average value has an acceptable standard deviation.

The combination of Fourier transform methods and infrared spectroscopy has caused a major resurgence of interest in this technique. The quality of the spectrum has been vastly improved even for very small samples in the milligram range, and so again this is a useful method for thermal analysis experiments. One significant advantage is that compounds with the cation in different oxidation states can often be differentiated. This technique has been used to follow the formation of iron(II) and iron(III) sulfates during the oxidation of pyrite.\(^{(53)}\) Although sulfate is known to be formed in significant quantities, it is often difficult to detect even by XRD perhaps because it is amorphous. The FTIR technique is very sensitive to the detection of sulfate vibrations, and so the formation and decomposition of the iron(II) and iron(III) sulfates in quenched samples of partially oxidized pyrite can be followed as a function of temperature. It was found that FeSO\(_4\) was the major species formed and that very little conversion of iron(II) to iron(III) took place under the experimental conditions used.

The technique was similarly used to determine CuO·CuSO\(_4\), which is one of the products formed during the oxidation of chalcocite. A peak at 439 cm\(^{-1}\) exhibited no interference by any of the other compounds present in the partially oxidized sample, and the measurement of its peak height for a set of standard samples was used to construct a calibration curve.\(^{(52)}\) Excellent quantitative results were achieved and the method had better detection limits than XRD. The results from the compositional analysis by XRD (Table 4) and the FTIR are given for partially oxidized samples of chalcocite against temperature in Table 5. Summation of the data for those samples in which all the phases were determined by these methods, that is at 570, 670 and 775 °C, gave values that were better than ±10% relative error. Hence these analytical methods provide a reasonable estimation of the phase composition of the sample at any particular temperature.\(^{(52)}\)

### 5.4.3 Decomposition of Sulfates

The decomposition of sulfates takes place in two stages as expressed by the Equations (8) and (9):

\[
2\text{MSO}_4(s) \rightarrow \text{MO} \cdot \text{MSO}_4(s) + \text{SO}_3(g) \quad (8)
\]

\[
\text{MO} \cdot \text{MSO}_4(s) \rightarrow 2\text{MO}(s) + \text{SO}_3(g) \quad (9)
\]

These reactions are detectable by mass losses in the TG curve.

5.5 Solid–Solid Reactions

A thermobalance can be used to follow reactions of the type represented by Equation (10):

$$A(s) + B(s) \rightarrow C(s) + D(g) \quad (10)$$

as for example in the curing of rubbers by elimination or condensation reactions. The change in mass can be used to follow the rate of cure and in fact this method has been adopted by industry for routine quality control purposes.\(^{(54)}\)

5.6 Analytical Applications

One of the major disadvantages of methods of mass loss analysis, such as loss on ignition measurements, is that the result is given as an undifferentiated mass loss from ambient temperature to 1000 °C. In contrast, TG methods permit the quantitative measurement of mass change as a continuous function of temperature. Hence in addition to being able to determine the purity of a high purity compound by measurement of the single mass loss associated with decomposition, in some circumstances several phases can be determined in a complex mixture. The required criteria are that each reaction is not interfered with by another reaction and that the stoichiometry of the product is known. Even when the reactions overlap to some extent, variation in the experimental conditions chosen can sometimes resolve the reactions sufficiently to permit individual quantification. Many examples of quantitative analysis by TG have been compiled by Earnest,\(^{(7)}\) in areas such as drugs, polymers, inorganic compounds, minerals, fuels, and waste products.

One of the most common measurements on a sample is for water, both adsorbed and water of crystallization, as well as other solvating agents. Usually these can be differentiated by control of the experimental variables, such as an isothermal hold so that the adsorbed water is completely removed before returning to the dynamic heating rate with subsequent determination of water of crystallization. For some salts, the water of hydration occurs in discrete steps, for example with CuSO\(_4\) · 5H\(_2\)O, which loses water in the ratio 2:2:1. Mixtures can be analyzed easily if the decomposition reactions are resolved. Plaster consists of a mixture of gypsum (CaSO\(_4\) · 2H\(_2\)O) and lime (Ca(OH)\(_2\)). Gypsum looses its water of crystallization between 100–150 °C, and the lime dehydroxylates between 400–500 °C, as demonstrated by Equations (11) and (12):

$$\text{CaSO}_4 \cdot 2\text{H}_2\text{O} \rightarrow \text{CaSO}_4 + 2\text{H}_2\text{O} \quad (11)$$
$$\text{Ca(OH)}_2 \rightarrow \text{CaO} + \text{H}_2\text{O} \quad (12)$$

Hence in a single experiment at a heating rate of 20 °C min\(^{-1}\), which would take 25 min, both phases can be determined with a greater accuracy than by any other method available.

Although the dehydration of gypsum appears as a single reaction in the above equation, it is a two step process as indicated by Equation (13):

$$\text{CaSO}_4 \cdot 2\text{H}_2\text{O} \rightarrow \text{CaSO}_4 \cdot 0.5\text{H}_2\text{O} + 1.5\text{H}_2\text{O}$$
$$\rightarrow \text{CaSO}_4 + 0.5\text{H}_2\text{O} \quad (13)$$

These two reactions can be resolved by alteration of the partial pressure of the water vapor above the sample. If the gypsum sample is sealed in a sample pan with a small leak, the water vapor trapped in the pan from the first reaction delays the commencement of the second step of the reaction by some 40–50 °C.\(^{(55)}\) This method has practical application in the cement industry. Gypsum is added to cement clinker in order to slow down the rate of setting. The two components are ground together, but heat generated in the process may cause decomposition of gypsum to the hemihydrate, which is undesirable. Hence the TG method can be used rapidly to analyze the gypsum/clinker mix for gypsum and hemihydrate, a task which again cannot be performed as quickly or accurately by any other method.

If two overlapping decomposition reactions are taking place and one of the reactions is reversible to its product gas, then introduction of that gas into the system will delay that decomposition and it will take

\(^a\) Calculated by difference.
place at a higher temperature. The decomposition of CaCO$_3$ is a reversible reaction, so the presence of CO$_2$ in the atmosphere will shift the decomposition temperature to higher values. It is possible, if the various thermodynamic constants are known, to calculate the effect of change in partial pressure of the evolved gas by use of Equation (14):

\[
\Delta G° = \Delta H° - T \Delta S° = RT \ln P
\]  

(14)

where $P$ is the partial pressure for this case of CO$_2$. Increasing the partial pressure from 0.1 to 1 atmosphere (1.01 x $10^4$ to 1.01 x $10^5$ Pa) of CO$_2$ produces a 138 °C shift in the decomposition temperature. Any other phase present in the system which was not reversible to CO$_2$ would be unaffected by the change in atmosphere.

One important application of TG/DTG has been in the study of high alumina cement (HAC). HAC is based on CaAl$_2$O$_4$, which can undergo a series of conversion reactions producing a change in volume which gives increased porosity with a concomitant loss in strength. It has been suspected that loss of strength was the cause of accidents which occurred in buildings constructed with HAC concrete beams. In order to assess the degree of conversion, and therefore to assess the degree of risk for the building, methods had to be developed to determine the phases present. DTA but also DTG was used and found to be acceptable. A typical DTG curve is shown in Figure 11.

The amount of Al(OH)$_3$ (written as AH$_3$) formed, which is one of the conversion products from CAH$_{10}$, is given by the peak height at just below 300 °C. The amount of unconverted CAH$_{10}$ is given by the peak height at 100 °C. Therefore the degree of conversion ($DC$) is given by a simple ratio, Equation (15).

\[
DC = \frac{[\text{AH}_3]}{[\text{AH}_3] + [\text{CAH}_{10}]} \tag{15}
\]

\[
\% DC = \frac{100[113]}{[113 + 15]} = 88\%
\]

The degree of conversion is, therefore, an empirical scale which can be used to estimate the likelihood of further conversion which might weaken the concrete or make it more permeable and, therefore, more vulnerable to chemical attack.

Changing the atmosphere from an inert one to a reactive one is a useful process. In an inert atmosphere many organic compounds can be decomposed and volatilized, and if the atmosphere is changed to air then some of the remaining material is oxidized with the formation of more volatile compounds. The residue is the ash. This analytical process has been used to carry out quantitative analysis on a variety of organic materials ranging from rubbers and plastics to coals. In the last case, the proximate analysis of a coal sample can be carried out by first heating in an inert atmosphere to 110 °C and holding until a constant mass is achieved. This mass loss enables the moisture content of the coal to be determined. The sample is heated at constant rate to 900 °C and held until constant mass is again achieved. This second mass loss enables the volatile matter to be determined. The furnace temperature is then lowered to 815 °C and the atmosphere changed to air, which burns off the fixed carbon and leaves the ash as a residue (Figure 12). Fourteen coals of widely differing composition were analyzed by the British Standard Specification 1016, Part 3 (1973), and by the TG method. In general the analysis values were similar. The TG analysis could be carried out in about 35–40 min per sample.
An additional magnetic step has been included in the proximate analysis method which permits the determination of pyrite. After the proximate analysis has been carried out, a magnetic field is switched on and any apparent increase in weight attributed to paramagnetic species such as Fe₂O₃. The ferric oxide is reduced to iron by the introduction of hydrogen at 400 °C. This produces a large apparent weight gain caused by the ferromagnetic effect. After cooling to room temperature the field is switched off and the apparent weight loss used to calculate the pyrite content. Good agreement was found between the TG magnetic method and the ASTM.

The analysis of rubber compounds can be carried out by a similar TG method. Rubbers typically contain polymers, extending oils and other organic compounds, carbon black and inorganic compounds. Heating the rubber in nitrogen volatilizes or decomposes the organic compounds, and decomposes the polymer, so that the first mass loss can be related to the total content of these compounds. Changing the atmosphere to air oxidizes the carbon black to give a second mass loss, and the residue is the inorganic components converted to their oxides. This analysis can be done in less than 20 min, and provides a rapid routine quality control method in the elastomer industry. The method can be largely automated with the computer system controlling the gas changes, heating rates and so on. The decomposition of the pure polymer should be checked to ensure that it does decompose completely and does not form a char. In some circumstances, TG can be used to quantify the components of polymer blends and block copolymers.

Sometimes, total phase analysis can be achieved by TG methods in conjunction with other analytical methods. Thus an iron ore containing a clay, goethite (FeOOH) and hematite (Fe₂O₃) was analyzed for the first two components by TG, and the total iron determined by spectroscopic analysis. The ferric oxide is reduced to iron by the use of a magnetic field and any apparent weight gain is attributed to paramagnetic species such as Fe₂O₃. The ferric oxide is reduced to iron by the introduction of hydrogen at 400 °C. This produces a large apparent weight gain caused by the ferromagnetic effect. After cooling to room temperature the field is switched off and the apparent weight loss is used to calculate the pyrite content. Good agreement was found between the TG magnetic method and the ASTM.

5.7 Kinetic Measurements

One of the major applications of TG has been for the determination of the kinetic properties of a solid compound as it decomposes or reacts. The use of TG for this purpose, however, has been the cause of much controversy, mainly through its uncritical usage resulting in considerable variation in the kinetic parameters published for a given reaction. The experimentalist would be well advised to read some of the critical reviews of the use of TG for kinetic studies, for example Brown and Flynn before commencing work.

Two equations are used to describe the kinetics of a reaction. The first one is the Arrhenius equation, which gives the relationship between the variation of the rate constant k with temperature (Equation 16):

\[ k = Ae^{-E/RT} \]

where T is the absolute temperature, A is the pre-exponential factor, E is the activation energy and R is the gas constant.

The second one is the rate equation, which describes the relationship between the fraction of material reacted, the rate of the reaction and time (Equation 17):

\[ \frac{d\alpha}{dt} = kf(\alpha)e^{-E/RT} \]

where \( \alpha \) is the fraction reacted in time t, and f(\( \alpha \)) is some function of \( \alpha \) which is related to the kinetic or reaction mechanism, for example diffusion control or shrinking sphere model. The term “reaction mechanism” does not always have this definition, however, and may also mean the determination of the chemical steps by which a reactant proceeds to product. The various forms adopted by the function f(\( \alpha \)) have been discussed elsewhere and are given in Table 6. The f(\( \alpha \)) function defines the shape of the TG/DTG curve. Changes in the properties of the sample and the experimental variables will cause changes in the rate of reaction and shifts in the TG/DTG curves, but unless the reaction mechanism changes, the shape of the curves should remain the same.

Combination of these equations leads to an Equation (18) of the form:

\[ \frac{d\alpha}{dt} = Af(\alpha)e^{-E/RT} \]  (18)

At a constant heating rate, \( T = T_0 + \beta t \), where \( T_0 \) is the initial temperature and \( \beta \) is the heating rate. Substitution for \( df \) gives Equation (19):

\[ \frac{da}{dT} = \frac{A}{\beta} f(\alpha)e^{-E/RT} \]  (19)

Rearrangement gives Equation (20):

\[ \frac{df}{f(\alpha)} = \frac{A}{\beta} e^{-E/RT} dT \]  (20)

which is the basic equation of the DTG curve, which when integrated is the equation of the TG curve. If the form of the function f(\( \alpha \)) is known, integration of the left hand side of the equation is straightforward, and gives the associated function, g(\( \alpha \)). If E is constant, the right
The isothermal approach involves rapidly heating the sample to some specific temperature and monitoring the mass change. The experiment is repeated with a new sample at another temperature, so generating a family of curves. The fraction reacted, $\alpha$, (the ratio of the mass loss at time $t$ and total mass loss for the reaction) is found for each temperature.

- The rising temperature or nonisothermal method requires that the sample is heated at a constant rate over the reaction temperature range. The value of $\alpha$ is given by the ratio of the mass loss up to temperature $T$ to the total mass loss of the reaction. Hence again $\alpha$ can be determined at several temperatures.

There are two main ways in which the data can be analyzed, the integral and differential methods. At first glance the former, as expressed by Equation (21), may seem the more attractive, as the measured mass loss is integral and the results can be used directly. Unfortunately, the right hand side of Equation (21) cannot be integrated analytically. Many attempts have been made to find appropriate approximations for the right hand side of the equation, but none of them seem to be entirely satisfactory. Differentiation of the data can be achieved, but this method also has its problems. The differentiation of the signal produces noise, which in turn affects the precision of the fit of the processed data with the various models. Both methods have their advocates, but so far no clear advantage has been shown for either.

The usual process for evaluation of the data is to fit values to the reaction models given in Table 6, and calculate kinetic data from the TG curves, although the user does not always know the algorithms being used, and the definition of the TG data by different mathematical analysis produces being investigated. It is also apparent that treatment of the various models. Both methods have their advocates, but so far no clear advantage has been shown for either.

The values of $E$ and $A$ affect the temperature range over which the TG curve is observed. One of the difficulties of dealing with kinetic work is that there are many choices available, for both the experimental approach and for ways of processing the data. The two main experimental approaches are:

- The isothermal approach involves rapidly heating the sample to some specific temperature and monitoring the mass change. The experiment is repeated with a new sample at another temperature, so generating a family of curves. The fraction reacted, $\alpha$, (the ratio of the mass loss at time $t$ and total mass loss for the reaction) is found for each temperature.
- The rising temperature or nonisothermal method requires that the sample is heated at a constant rate over the reaction temperature range. The value of $\alpha$ is given by the ratio of the mass loss up to temperature $T$ to the total mass loss of the reaction. Hence again $\alpha$ can be determined at several temperatures.

The right hand side of the equation can be integrated leading to Equation (21):

$$g(\alpha) = \frac{A}{B} e^{-ER/T} dT$$

(21)
acceleration thermal analysis, temperature jump, and modulated TG. Each of these methods has its own method of calculating the values of $A$ and $E$.

The general consensus amongst kinetic scientists appears to be that there is no one method which has general applicability to all systems under investigation. Each system needs to be considered for both choice of method and data processing technique, and the ability to make the right choice comes with experience. However, these techniques are very useful if the purpose of the study is to obtain kinetic values to provide a quantitative comparison of materials for a specific use, or to assess the properties of similar samples prepared by different methods.

2 Some Basic Features of Electron Spectroscopy
Abbreviations and Acronyms

1 HISTORICAL BACKGROUND

Röntgen’s discovery of X-radiation in 1895 in Würzburg resulted in an immediate breakthrough, not just in physics but also in society, the latter mainly because of the sensational radiological applications of X-rays. Within a short time it also led indirectly to the discovery of radioactivity by Henri Becquerel. The discovery of X-radiation opened the gate to modern atomic physics, while the discovery of radioactivity did the same for nuclear physics. Later on, the discovery of X-ray diffraction made fundamental contributions to the understanding of atomic and crystal structures. Secondary electrons were soon observed in the scattered radiation when X-rays hit a sample. Development of the corresponding electron spectroscopy took much longer to reach maturity.

Röntgen carefully studied and described most of the properties of the radiation which he himself named X-radiation. With great experimental skill Röntgen attained order in a field that had previously been completely outside human experience. The phenomenon of diffraction of X-rays in crystals opened up two fields of fundamental importance in physics and chemistry, and later on in biology. First, very accurate X-ray wavelengths could be measured giving new and precise insights into the interior of atomic structures. Second, crystal structures, and distances and directions between lattice points of various crystal and molecular structures, could be calculated. All this has had a tremendous impact on atomic and molecular physics and, during the last decades, even on the understanding of life and reproduction, etc.

To go back to the time following the discovery of X-rays, Barkla and others had, by simple means, produced proof of some properties of X-radiation which had significance for the further development of atomic physics. After penetrating aluminium foils the “soft” part of the radiation was quickly absorbed. Left behind was a rather “hard” radiation. Allowing this harder radiation to strike an arbitrary plate, one could find three different components (Figure 1) in the scattered radiation. The first component consisted of scattered radiation of a similar kind to the impinging radiation. The second component was secondary X-radiation which was softer than the impinging radiation and characteristic of the irradiated material. From the study of this characteristic (fluorescence) radiation Barkla could distinguish between two series of radiation, which he called K and L fluorescence radiation. For a certain element the penetration of the K-radiation could be 300 times higher than that of the L-radiation. From these early observations X-ray spectroscopy was later developed by means of more and more refined X-ray diffraction methods. X-ray spectroscopy made possible atomic analysis of different materials and led to the discovery of new elements such as hafnium and rhenium. The shell structure of the atoms could be investigated by X-ray spectroscopy.

The third component of the scattered radiation was found to consist of electrons, which were expelled from the irradiated material. What happened in this field of spectroscopy? For a very long time it was overshadowed by the successful study of X-ray spectroscopy. In the 1920s spectroscopic investigations of the secondary electrons, the “photoelectrons”, were begun, for example by H. Robinson in England and M. de Broglie in France. They showed, by magnetic deflection of the electrons, that this component also contained information on the shell structure of the atom and that one could obtain approximate values for the binding energies of the electrons in the different shells. This field turned out to be much more difficult to master, and the accuracy was low.

In our laboratory in Uppsala, interest in this third component began early in the 1950s. For some time previously we had been concerned with techniques to investigate electrons emitted in radioactive β-decay. A suitable way to investigate the γ-radiation was to cover the radioactive sample with a thin lead foil and to record the photoelectrons expelled from the foil using an electron spectrometer. We were finally able to observe and measure even the inherent widths of internal conversion-electron lines due to the finite widths of the atomic levels involved in the conversion process during the nuclear decay. To observe such phenomena a resolution of $1 \times 10^4$ at these energies, around 100 keV, was required. The investigations were performed using a magnetic double-focusing iron-free spectrometer with a large dispersion ($R = 30\text{ cm}$). It was tempting to go

back to Röntgen’s original discovery and more precisely to the third component mentioned previously, to see if new methods could be applied to atoms, molecules and solids using an X-ray tube instead of nuclear γ-radiation. For this purpose an iron-free magnetic double-focusing instrument was constructed and used to investigate electron energies some orders of magnitude less than in nuclear β-decay. For X-ray energies double-focusing electrostatic instruments were later designed.

During the 1950s and the 1960s our work finally led to the development of an electron line spectroscopy technique which was characterized by narrow electron lines from the materials excited by X-radiation and ultraviolet radiation. The recorded electron lines were well defined by widths set by the inherent atomic widths themselves. Details of the spectroscopy technique, which had applications in many fields, were published in 1967 in the book “ESCA: Atomic, Molecular and Solid State Structure Studied by Means of Electron Spectroscopy”, followed in 1971 by “ESCA, Applied to Free Molecules”, both authored by our group.

Electron spectroscopy is nowadays an independent alternative to X-ray and other spectroscopies and contributes much new information about the properties of matter. Surface science and technology in particular makes use of electron spectroscopy as a convenient tool to characterize surface conditions and reactions. Applications are found in many other areas on the borders between physics and chemistry. To emphasize these later aspects the acronym ESCA (electron spectroscopy for chemical analysis) was introduced. The acronym XPS (X-ray photoelectron spectroscopy) is also used.

2 SOME BASIC FEATURES OF ELECTRON SPECTROSCOPY

In electron spectroscopy the sample is introduced into a vacuum and irradiated by soft X-rays, ultraviolet light, laser light, or synchrotron radiation. In addition, an electron beam can also be used to cause Auger electron scattering spectroscopy. A certain number of the electrons which are expelled from their atomic bonds may leave the surface layer without energy loss, the scanning depth being set by the energy-dependent mean free paths. An electrostatic lens system collects and focuses the electrons onto the slit of the electron analyzer. An extended detector is situated in the focal plane where the different electrons are simultaneously being recorded. These events appear on the screen of a computer as a set of separate electron lines (see Figure 2). The lines characterize the examined substance, the elemental composition and the chemical bonds.

Solid materials with elements over the whole periodic system can be examined, as well as gases and molecular beams down to low pressures of ~10⁻⁵ torr. The technique has also been applied to liquids and solutions. Applications of electron spectroscopy using synchrotron radiation and laser radiation for excitation have been increasing during more recent years.

Figure 3 illustrates an atom which is bound to other atoms in molecular valence bondings, adsorbed or chemically bound to a surface. To eject electrons from the inner part of an atom (the “core” region) harder radiation is required than for the external “valence” electron region. When an electron is emitted a hole is created in the electron shell. This is immediately followed by a relaxation of the other electrons which thereby adjust themselves to the new potential by means of “shrinkage” and “flow” in the surrounding electron cloud. The hole has a particular, very short, lifetime (<10⁻¹⁴ s) before it is filled by an electron from some external shell. The atom can dispose of the released energy either in the form of an X-ray photon or by emitting another (Auger) electron. In the latter case three levels are involved (e.g. LMM, etc.). Such electrons are recorded together with the primary emitted photoelectron spectrum. One advantage of exciting Auger electrons by X-rays instead of electrons is the great improvement in signal-to-noise ratio. However, using an electron beam for excitation of Auger electron enables a high spatial resolution since the primary electron beam can be focused to a very small spot (<10 nm) on the sample, suitable for scanning and high resolution imaging.

When a chemical compound is formed between two or more atoms it causes a redistribution of the external valence electrons of the atoms which are responsible for the chemical bonds. The electric potential around a certain atom in the molecule will then be changed to an extent which is dependent on the specific nature of the chemical bond in the different cases (e.g. different “states of oxidation”). This new electric potential influences the bond strength of the inner electrons which surround the atomic nucleus and the consequence of this is a “chemical shift” in the recorded electron spectrum. This information is extremely important in electron...
XPS AND AES: INTRODUCTION

spectroscopy. One can for example easily distinguish, even at fairly modest resolutions, between metallic atoms and those which have been oxidized at the surface layer.

A great number of ESCA instruments are now in operation and the applications are increasing. Some are provided with X-ray monochromators for high-resolution work and some are combined with water-cooled rotating X-ray anodes. It is this combination which offers the best advantages for high resolution at high intensities in ordinary laboratories. Here and also in synchrotron laboratories the recorded electron line widths are ultimately set by the inherent level widths. An X-ray monochromator, using the (1010) plane of toroidally bent quartz wafers mounted in an assembly for the Al Kα radiation, significantly improves the conditions for accurate deconvolutions at the analysis of the spectra, since the lines get narrower and the signal-to-noise ratio is enhanced. The electron lines due to X-ray satellites situated close to the real line structures are eliminated and so is the background noise due to Bremsstrahlung. Ultrasoft X-ray lines are furthermore available in the Mz X-radiation from yttrium, zirconium, etc. in the energy region of ~150 eV. These can be focused by multilayer X-ray mirrors at high reflectivity.

**ABBREVIATIONS AND ACRONYMS**

ESCA       Electron Spectroscopy for Chemical Analysis
XPS       X-ray Photoelectron Spectroscopy
The use of X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES) to analyze the surface composition and chemical environment of solids has been well established since about the early 1970s. These approaches find many applications in both basic and applied scientific investigations. The basic principles, i.e. surface sensitivity, the experimental observations employing these procedures, and the working methods, are described. The instrumentation utilized with the commonly available equipment for these approaches is summarized also.

1 INTRODUCTION

The ability to analyze the outermost few atomic layers of solid surfaces has expanded greatly since the early 1970s.
reduced cost, or are targeted for the replacement of older components. Some parts of XPS and AES systems, notably vacuum components, can have useful lifetimes of decades, so that component replacement can be cost effective in certain situations. Components are available from a wider variety of sources than just system suppliers. Some lower-cost XPS and AES analysis systems are available that are designed for many routine applications, but will still have many fairly advanced features. Software for data analysis that has special capabilities is being offered from many sources besides that supplied with complete analysis systems.

2 BASIC PRINCIPLES

An extended discussion of the basic principles involved with AES and XPS is beyond the scope of this article; other sources give more detailed explanations. However, many of the important factors are discussed as they relate to the available instrumentation and experimental procedures.

2.1 Surface Sensitivity

The most basic question that has to be asked about XPS and AES is: Why are these techniques sensitive to the surface region of solids? Both XPS and AES make use of the fact that electrons with kinetic energies from about 30–2500 eV (this is the range of almost all of the electrons typically analyzed by either XPS or AES that are ejected from an atom in a solid) will have an inelastic mean free path (IMFP or \( \lambda \)) of about 0.5–3 nm. The IMFP is defined as the average distance that an electron will travel before it undergoes an inelastic collision with another electron or nucleus of the matrix constituent atoms. Thus, very few electrons created at depths greater than two to three times the IMFP will leave the bulk with the characteristic photoelectron or Auger electron kinetic energy with which they were created. Using data from experiments with very thin overlayers of one element deposited on another, it has been ascertained that the intensities of the substrate signal vary approximately as \( 1/e \) with film thickness. In some cases it has been suggested that the IMFP for organic compounds and films is greater than IMFPs for metals and inorganic layers, perhaps being in the 8–12 nm range. These proposed values have been questioned and somewhat smaller values have been suggested from the results in other investigations. Based upon the findings from many studies, IMFPs have been subdivided by Seah and Dench into three material-dependent subclasses: elemental, inorganic, and organic. Even with these subdivisions, there still is considerable scatter in the data. More recent individual reports are usually in general agreement with the earlier work. It also has been proposed by Seah and Dench that the IMFP follows the relationship (Equation 1)

\[
\lambda = aE^b + \frac{c}{E^d}
\]  

(Equation 1)

where \( a \) is a material-dependent constant, \( b \) is an exponent of 0.5, \( c \) is a constant that depends on the class of material, and \( E \) is the kinetic energy of the ejected electron. The second term predominates at lower kinetic energies, i.e. less than about 100 eV. An idealized representation of the IMFP of electrons as a function of kinetic energy is given in Figure 1, based on Equation (1) for three elements. Note that there is a minimum value for the IMFP of about 0.5 nm for kinetic energies in the 100 eV region. Then the IMFP increases slowly as the kinetic energy becomes larger.Others have suggested that \( b \) has a value near 0.75. Regardless of the various suggested functional dependencies for the IMFP, the experimentally determined values all are approximately within the region shown above. Jablonski has questioned the functional relationship in Equation (1) and has proposed the Equation (2)

\[
\lambda = \frac{aE}{ln(\gamma E)}
\]  

(Equation 2)

with \( a \) and \( \gamma \) being material constants. (The constant \( a \) in Equation 2 differs from that in Equation 1). Equation (2) follows much of the reported experimental data at kinetic energies of 500 eV and greater, but there are deviations for electrons with lower kinetic energies.

Other parameters have been proposed to account for the surface sensitivity of XPS and AES. These have included the attenuation length (AL), defined as the average distance that an electron travels between successive inelastic collisions as given by a particular

![Figure 1](image_url)
model. More recently, a quantity called the depth distribution factor (DDF) has been defined as the emission probability from a given distance below the surface for the escape of an Auger or photoelectron. The magnitude of these other parameters does differ from the IMFP, and sometimes there are variations of about 30% or more. However, these differences still do not change the basic fact that electrons in the kinetic energy region detected in almost all conventional XPS or AES experiments originate from only the first few atomic layers of a solid. For convenience the term IMFP will be used in this article. Different approaches have been used to predict IMFPs on a fundamental basis of material properties. This entire topic has been reviewed extensively by Powell.

Many Auger transitions, especially for most metals, are in the 50–100 eV region, but often there are overlapping peaks if other elements are present. With XPS the use of grazing take-off angles combined with angular resolution detection increase surface sensitivity; this topic will be treated in detail later. Either approach often gives enhanced surface sensitivity compared to more typical XPS or AES analyses.

2.2 X-ray Photoelectron Spectroscopy

The photoelectric effect in which a valence or core electron is ejected when irradiated with soft X-rays forms the physical basis of XPS. The Einstein relationship (Equation 3) governs the process

\[ E_{KE}^F = h\nu - E_{BE}^F - \phi_{sp} \]

where \( E_{KE}^F \) is the measured kinetic energy (peak maximum) of the ejected electron with respect to the Fermi level, \( h\nu \) is the photon energy (for XPS this is usually in excess of 1 keV), \( E_{BE}^F \) is the binding energy of the ejected electron with respect to the Fermi level, and \( \phi_{sp} \) is the work function of the spectrometer. This last factor is constant for a particular instrument and should vary little during its lifetime. A diagram of the photoejection process is shown in Figure 2. A simple rearrangement of Equation (3) gives the binding energy. This value is usually reported with XPS data, as it is independent of the photon energy. All of the elements except hydrogen and helium can be detected by XPS, but there are some cases where the presence of hydrogen has been inferred from XPS spectra. Each element has its own unique set of binding energies, so that identification can be made of the element or elements that are observed in an XPS spectrum. In a few cases there is an overlap of lines from different elements. However, there are other lines that will be observed that permit differentiation of the elements present in those overlapping situations, unless the signal is due to a very small amount of an individual element that is overwhelmed by that of the another element.

The energy level of the ejected photoelectron is indicated by atomic notation. For example, in a typical XPS spectrum of Ag, as shown in Figure 3, peaks due to the 3s, 3p, 3d, 4s, 4p, and 4d levels of Ag are observed. The spin–orbit split of the 3p and 3d levels can also be seen. The lower multiplicity levels, i.e. the 3p1/2 and 3d3/2 lines, are on the left side of these respective doublets. The higher intensity lines are the 3p3/2 and 3d5/2 peaks. The ratio for the intensities of the doublets is calculated from the total angular momentum, \( j \), for the level being considered using \( j\pm j \) coupling, i.e. \( j = I + s \) where \( I \) is the orbital angular momentum and \( s \) is the spin quantum number. For p levels, the p1/2 peak has twice the relative intensity of the p3/2 line. The relative ratios for d levels is 1.5 (d5/2 to d3/2) and for f levels is 1.33 (f7/2 to f5/2). The deeper core levels for Ag could not be observed, as their binding energies are greater than the characteristic photon energies of the most common X-ray sources employed in XPS (1253.6 and 1486.6 eV for Mg and Al, respectively). In addition to the photoelectron peaks, several Auger transitions are found, as indicated in the spectrum. These lines are due to the holes created in the d3 levels in the photoemission process; details about the Auger mechanism are given later. Binding energy values for all elements have been published together with spectra from most elements. A database of binding energies for use with a personal computer has been compiled under the direction of the National Institute of Standards. This database has thousands of entries with numerous compounds; it also lists many Auger transitions. A review of the available databases has been made.

Besides elemental identification in the surface region, information about the chemical environment of these elements usually can be deduced from XPS spectra. For example, there is a difference of about 5 eV between the 2p3/2 peak of metallic iron (707 eV) and Fe2O3 (712 eV). For sulfur, there is about an 8 eV separation

![Figure 2](image-url)
Figure 3 An XPS survey scan of sputter-cleaned silver with the energy of the photoelectron transitions in terms of binding energy using a Mg Kα X-rays. The X-ray excited Auger peaks are indicated by (A). The split of the 3d and 3p levels can easily be seen with the 3p1/2 and 3d3/2 peaks on the left side of the respective doublets. The shoulder on the right-hand side of the 3d3/2 peak is due to Kα3,4 X-rays.

in the 2p level between S2− and SO42− (approximately 161 and 169 eV, respectively). For some elements, such as Cu, these shifts are smaller, and other spectral features, namely the use of Auger lines and ‘shake-up’ peaks (considered below), have to be employed to gain chemical information. In addition, there can sometimes be variations in binding energy with atomic environment, for instance aluminum bound either tetrahedrally or octahedrally.

The accurate determination of binding energies can be made by comparison to standard values that have been measured with metals. Most of these determinations have error limits of ±0.03 eV. A number of instrumental and experimental factors have been evaluated that affect these measurements. In addition, the zero point of the binding energy scale is set by the Fermi edge of a metal. Ni has been used for this purpose, but Ag has been suggested to have a more distinct Fermi edge. Surveys with instruments at many laboratories from different manufacturers have been conducted, and it has been found that most users usually agree to about 1 eV with oxide samples. The effort required to obtain this level of agreement usually involved following manufacturers’ procedures and some sample preparation that usually is not very time-consuming. With an individual instrument in a typical laboratory environment, the position of some metal peaks can usually be determined to within 0.05 eV or less. Sometimes special methods are employed to determine accurately the peak position. Unfortunately, under typical laboratory conditions, errors an order of magnitude larger often occur. In some very careful studies, small binding energy differences between the surface and bulk atoms in metals are observed; this topic has been reviewed elsewhere. With alloys there can be small shifts in the Fermi level that will affect measured binding energies. Similar findings have been made with bimetallic clusters. Smaller clusters have higher binding energies than the bulk values, an effect suggested to be due to nonmetallicity increasing as size decreases.

Many procedures have been utilized to calculate binding energies and binding energy shifts. Empirical methods employing the charge on an atom (computed by molecular orbital methods and compared to a standard material) have been used. Other procedures, such as Hartree–Fock calculations and electrostatic models, have also been employed. The equivalent core approximation, set up in a manner similar to the Born–Haber cycle, has also been applied. Further information on these computational procedures is available elsewhere.

When insulators are being analyzed there is the complication of charging. This effect is observed when the surface of the specimen becomes positively charged, because more electrons leave the surface region than are replaced by those from the bulk. The peak maximum will...
shift to lower kinetic energies (higher binding energies), sometimes by tens of electron volts. Usually a charge equilibrium is established after a reasonably short time. Sometimes a spectrum will not be observed, or the peak shape will be badly distorted. It has been suggested in some cases that surface layer atoms will have a different charging shift from those atoms below the surface.\(^{(50,51)}\) Also, lateral charging across the surface has been observed due to a nonuniform X-ray flux and sample mounting procedures.\(^{(52,53)}\) Even conductors deposited as clusters on insulators can experience charging. In addition, the cluster size and their distribution can affect observed binding energies.\(^{(54)}\) The effects of substrate conductivity and photoelectron cross-section on differential charging have been explored for some polymer systems.\(^{(55)}\) With uniform polymer layers on NaCl the effects due to the photoelectron flux from both layers and the electron energy from a flood gun (considered later) were found to be important factors in charging behavior.\(^{(56)}\)

Several approaches can be tried to overcome, or at least minimize, charging effects in XPS. The Auger parameter (discussed below) can be used, because it is assumed that both the photoelectron and Auger peaks will be shifted by the same amount. Then a comparison is made with previously reported data. Another method is use of the adventitious carbon peak present on almost all sample surfaces that have been exposed to the atmosphere.\(^{(57)}\) Then, all other peaks are referenced to the position of this peak, that is usually is set to a value of 284.6 or 285 eV. This procedure has been criticized because it assumes that the binding energy position of this peak will always be the same.\(^{(58)}\) Measuring the binding energy of ion-implanted Ar (discussed below) has been suggested as a reference point to correct for the charging effect.\(^{(59,60)}\) However, this technique might suffer from shifts in the Ar peak position due to extraatomic effects being different with various materials. Another approach is the use of a flood gun. A high transmission screen just above the sample has been observed due to a nonuniform X-ray flux and sample mounting procedures.\(^{(52,53)}\) Even conductors deposited as clusters on insulators can experience charging. In addition, the cluster size and their distribution can affect observed binding energies.\(^{(54)}\) The effects of substrate conductivity and photoelectron cross-section on differential charging have been explored for some polymer systems.\(^{(55)}\) With uniform polymer layers on NaCl the effects due to the photoelectron flux from both layers and the electron energy from a flood gun (considered later) were found to be important factors in charging behavior.\(^{(56)}\)

Occasionally degradation of specimens occurs because of X-ray irradiation. This can often be observed as a diminution of a peak of an element in one oxidation state with the increase in intensity of another, such as for perchlorate to chloride.\(^{(64)}\) This effect has also been noted with some polymers. In some instances it has been suggested that sample heating from the X-ray source may cause specimen degradation. In many situations this problem can be minimized by using a monochromatic X-ray source (discussed below). Also, many newer instruments can collect data much faster than was possible with older equipment, so that the time a sample is exposed to X-rays, and therefore the possible damage, is greatly reduced.

The use of X-ray-excited Auger peaks is usually based on the Auger parameter \(\alpha\), which is defined (Equation 4) as

\[
\alpha = E_{\text{KE}}^{F}(j, k, l) - E_{\text{KE}}^{C} + h\nu
\]

or

\[
\alpha = E_{\text{BE}}^{F} - E_{\text{BE}}^{C}(A) + h\nu
\]

Here \(E_{\text{KE}}^{F}(j, k, l)\) is the kinetic energy of the Auger transition referenced to the Fermi level (where \(j, k,\) and \(l\) denote the energy levels involved in the Auger transition, discussed in more detail below) and \(E_{\text{BE}}^{C}(A)\) is the energy position of the Auger peak on the binding energy scale. This definition usually is referred to as the modified Auger parameter, as an earlier definition sometimes gave negative values. Note that the Auger parameter is independent of the X-ray source employed to obtain a spectrum. The Auger parameter can also be used to determine the chemical environment of the detected elements. Often the differences in the Auger parameter are larger than the changes observed in the photoelectron peak energy alone. In many systems the peak shifts found for Auger transitions are larger than those for photoemission lines.\(^{(65)}\) Peak positions will be shifted by charging: about the same amount for both photoelectron and Auger transitions. This can help in making assignments for the chemical state information in cases where a specimen is undergoing charging. Further details on the use of Auger parameters for many materials have been reviewed.\(^{(66)}\)

Shake-up peaks result from a discrete energy loss of a core electron when a valence-band electron is ejected into an unoccupied conduction band during the photoemission event. Very strong shake-up peaks are observed with some transition metals with changes in the oxidation state, for example oxides versus the pure metals.\(^{(67)}\) With some metals, the shake-up peaks may be approximately 10 eV higher in energy than the main line. Shake-up peaks are observed also in polymers where there are conjugated \(\pi\) systems.\(^{(68)}\) In these cases, the shake-up peaks are about 5 eV above the main photoelectron line. The intensity of the shake-up peaks in these cases is much less than the main photoelectron line.

The valence band (VB) region of XPS spectra is not usually used extensively with X-ray excitation. In Figure 3 this area is denoted as the 4d peak. There are two reasons for this spectral region being neglected. First, the intensity
of the peaks is weak compared to the core level lines with the normal X-ray sources. Second, all of the elements in the sample under study will contribute to the spectrum in the VB region. Thus, making use of this portion of the spectrum is usually more difficult for obtaining elemental and chemical information for a specific element. Better VB spectra can be obtained with special sources, such as a He lamp that has a photon energy source of 21.2 eV. Such sources can be an attachment to a spectrometer.

However, the situation has changed with more efficient instruments using regular X-ray sources. First, as noted earlier, newer spectrometers can obtain spectra with much greater intensity than with earlier equipment. This allows data to be acquired in this region much more quickly. Secondly, the use of Xo calculations (a procedure used to compute the energies and intensities of atomic levels for chemical species) to model the VB spectra can be done on a routine basis with a personal computer. With this approach Sherwood and co-workers have been able to discover differences in surface species that could not be found by using just core level peaks alone.\(^{(69,70)}\) This technique has opened new avenues for analyses in many systems.

The surface sensitivity of XPS can be enhanced by analyzing electrons that leave the surface at a near glancing angle; this technique is called angular resolved X-ray photoelectron spectroscopy (ARXPS). A simple model of a thin uniform layer of material B at a depth \(d\) on a substrate A illustrates this effect. The intensity of the substrate signal has been approximated by Equation (5)

\[
I_a = I_a^0 \exp \left( -\frac{d}{\lambda \sin \theta} \right)
\]

where \(I_a\) is the measured intensity of the substrate signal, \(I_a^0\) is the signal of A without B, and \(\theta\) is the angle at which the detected electrons leave the sample relative to the surface normal. The relationship for the signal intensity of the overlayer is (Equation 6)

\[
I_b = I_b^0 \left( 1 - \exp \left( -\frac{d}{\lambda \sin \theta} \right) \right)
\]

where \(I_b\) is the intensity of the overlayer signal and \(I_b^0\) is the intensity for an overlayer of several \(\lambda\). Nondestructive analysis of thin films, i.e. without using ion beams, can be performed by this approach, but added factors need to be considered.\(^{(71–73)}\) Angular resolved procedures can also be used in AES\(^{(74)}\). The experimental procedures for using ARXPS are given later.

### 2.3 Auger Electron Spectroscopy

There are two pathways for the atom to relax when a core hole is created. One way is for an X-ray to be emitted when an electron from a higher orbital falls into the hole (X-ray emission). The creation of an Auger electron is the alternative mechanism. In this case, an electron from a higher orbital falls into the empty hole while another electron is ejected from the same or even higher energy level of the atom. This process is illustrated in Figure 4.

The energy relationship for the Auger process with respect to the Fermi level is given by Equation (7)

\[
E_{KE}^F(j, k, l) = E_{KE}^F(j) - E_{KE}^F(k) - E_{KE}^F(l) - U
\]

where \(E_{KE}^F(j)\) is the binding energy of the electron ejected during the initial ionization event, \(E_{KE}^F(k)\) is the binding energy of the electron that falls into the empty level, \(E_{KE}^F(l)\) is the binding energy of the ejected electron, and \(U\) is the hole–hole repulsion energy. This last term takes into account the fact there are two empty electron states in the excited atom; \(U\) is of the order of 1–10 eV. It should be noted that Auger energies often are given with respect to the vacuum level. The difference between the Fermi level and vacuum level is about 5 eV. There are more complex decay mechanisms found with some materials that contribute to the overall Auger transition beyond the description given above. However, these effects usually do not change the energy of the observed Auger transition to the extent that elemental identification cannot be made.

Details about these more complex decay pathways have been reviewed.\(^{(75–77)}\) AES is similar to XPS in that all of the elements except hydrogen and helium can be detected, but the presence of hydrogen has been observed by line shape changes.\(^{(78)}\)

Auger electrons can be created in several ways. However, for surface analysis the two predominant methods are from an electron beam with a kinetic energy of about 2–10 kV, or from an X-ray source. The electron beam needs to have at least 2–3 times the kinetic energy to observe the Auger transition of interest in order to observe the transition with reasonable signal strength. The X-ray source has to have an energy greater than the binding energy of the initial core level that participates...
in the observed Auger transition. Beam currents usually range from tens of microamperes to about a nanoamperere. In certain Auger spectrometers, the beam diameter can be adjusted to be less than 20 nm. Compilations of Auger spectra have been made for routine elemental identification. A high-resolution AES database has been constructed for many elements with an absolute intensity scale. Instrumental contributions have been removed from the data so comparisons to any instrument can be made.

AES lines are identified with X-ray notation. AES spectra in surface analysis are displayed in two modes, derivative and integral. Details about the presentation methods for AES spectra are given later. For example, if an electron is ejected from the 1s level of Si, and a 2p$_{3/2}$ electron falls into the empty hole and another 2p$_{3/2}$ is ejected from the atom, the transition would have the notation KL$_2$L$_3$. The energy difference between the 2p$_{3/2}$ and the 2p$_{1/2}$ levels in Si is small (about 0.6 eV) in comparison to the observable width of this Auger transition. (The 2p$_{3/2}$ and the 2p$_{1/2}$ levels in Si levels can be resolved with many XPS instruments.) Thus, the overall observed peak is a combination of these levels, and its notation for this example is KL$_{2,3}$L$_{2,3}$. If valence electrons are involved in the Auger transition of interest, they are often denoted by V. Examples of this are illustrated in Figures 5 and 6, which show the AES spectrum of Li$_2$SO$_4$ in both integral and derivative display modes. In this case a hole in either the 2p$_{3/2}$ or 2p$_{1/2}$ level for S is filled with an electron falling from a valence level and ejecting another valence electron. For this overall Auger peak the notation would be L$_{2,3}$VV.

Chemical effects often are observed in AES. There are shifts in the position of the observed peaks for some elements depending on the chemical state; for example, the KL$_{2,3}$L$_{2,3}$ peak for Si is observed at 1616 eV whereas this line is at 1608 eV for SiO$_2$. In other instances there is both an energy shift and a change in the peak shape. For example, with the S L$_{2,3}$VV level, peaks of sulfides and sulfates are approximately 150 eV with a doublet 126 and 140 eV, respectively. The peak at 150 eV in Figure 6 is due to the reduction of a sulfate type species by the electron beam. Most of the observable peak shape differences involve transitions with valence electrons. This method of identifying chemical species can be employed sometimes and often is referred to as fingerprinting.

When AES was first utilized for elemental identification in surface analysis, the derivative mode of spectral display was used. The signal levels of the integral peaks were very low compared to the overall intensity of the spectrum and this usually made observation of Auger peaks difficult. However, by taking the derivative of the spectrum, the Auger peaks were much easier to observe visually. In addition, the sloping background was reduced or eliminated. The compilations of Auger spectra usually are of derivative spectra, and the peak position is defined as the minimum of the peak. With improvements in analyzers and electron detectors, many spectra are now reported with integral data. Some compilations of Auger data contain spectra displayed in this format also. The choice of display method is made by the author or authors of a report. There is a difference in the position of the peaks between the methods. The peak maximum in the integral display is at the zero cross-point in the derivative mode representation. The energy difference usually is only a few electron volts between these methods unless there is a badly distorted peak.

![Figure 5](image1.png)  
**Figure 5** The electron-excited AES spectrum of Li$_2$SO$_4$ observed with an electron beam excitation of 500 V in the nonderivative display mode is shown. The small bump at about 140 eV is due to the sulfur LVV transition. The strong peak at 500 eV is due to the reflected primary electron beam. (Reproduced from D.E. Ramaker, J.S. Murday, N.H. Turner, ‘Extracting Auger Line Shapes from Experimental Data’, *J. Electron Spectrosc. Relat. Phenom.*, 17, 45–65 (1979).)

![Figure 6](image2.png)  
**Figure 6** The derivative AES spectrum from Figure 5.
Accurately determined values for AES transitions have been made in the same fashion as those in XPS. Values for some metals with errors of ±0.03 eV have been determined. The transitions used in these instances are unusually sharp for Auger peaks. The accuracy of these determinations is much greater than almost all reported values in general analysis.

Charging can be a much more serious problem when using electron beam AES compared to XPS with insulating samples. When charging happens, peaks will be shifted to higher kinetic energies or huge peaks will appear in the spectrum that are much larger than any observable Auger transition. When the latter phenomenon occurs, there is little if any possibility that useful information will be obtained. Also, the extent of charging can change from sweep to sweep. Several approaches can be taken in an attempt to overcome this problem. These include changing the beam voltage and current to try to balance the incident beam current with the secondary electron emission. Unfortunately, in some cases the beam voltage has to be lowered to a potential where some transitions will not have a strong signal. In a few instances the transition energy will be above the beam voltage that reduces charging. Tilting the specimen to a more grazing angle with respect to the electron beam has sometimes been successful. Rastering the beam over a large area of a specimen is occasionally effective. Wrapping the sample in metal foil with a small hole that exposes only a small part of the specimen is another approach that has sometimes been effective. No single procedure is successful in all cases, and the analyst has to be prepared to try several methods. Further information about charging in AES is available.

Another effect that sometimes has to be considered in AES is sample degradation, which occurs more frequently than in XPS. An example of this effect has been observed with α-Al₂O₃ and some sulfates. Some of the same approaches tried to overcome charging can be used to reduce or eliminate degradation, namely changes in the beam current and voltage, rastering, etc. The local temperature may rise where the beam strikes the specimen and may also play a role in specimen degradation. Sample degradation in AES has been reviewed elsewhere.

3 INSTRUMENTATION

There are many components that comprise an XPS or AES spectrometer, and some commercially available components or those built from component systems are capable of performing both XPS and electron-excited AES. Often there are compromises with such multi-technique systems. The various items and experimental procedures used with XPS and AES spectrometers discussed here are the vacuum system, sample handling and introduction, excitation sources for the production of photoelectrons or Auger electrons, the detection of these electrons, and the data collection and handling procedures. Only passing references are made to the associated electronics. More details about other experimental procedures are available elsewhere.

3.1 Vacuum Systems

Both XPS and AES require vacuums in the 10⁻³ Pa region (1 Pa is 1 N m⁻² and is approximately 7.5 × 10⁻⁳ torr). With pressures above this value, a significant number of the electrons that are to be analyzed will undergo collisions with the residual gas in the system and will not be detected. Now, almost all commercially available or component-built systems are capable of achieving pressures in the ultra high vacuum (UHV) regime (about 10⁻⁸–10⁻⁹ Pa). It should be noted that it will take several hours for a surface to be covered statistically (assuming that every molecule sticks to the surface) at these pressures from background gases in the analysis chamber. This means that once a clean surface has been produced, it should be possible under normal operating conditions to characterize completely most materials by either or both XPS and AES, without significant contamination from background gases in the vacuum system. Not all combinations of clean surfaces and gases will have a sticking coefficient of unity (i.e. upon each collision with a surface a gas molecule or atom will be adsorbed); this reduces the sticking coefficient as a potential problem in many analysis situations. A handy rule-of-thumb is that a surface will be covered in one second at a pressure of 1 × 10⁻⁶ torr if each molecule or atom has a sticking coefficient of one; this quantity is called a Langmuir. The time for a surface to be statistically covered will depend on the molecular or atomic weight of the species present in the vacuum chamber.

The achievement of UHV pressures can be accomplished in many ways. Consideration has to be given to the materials and techniques used in both the construction of a vacuum chamber and the components that are employed for analytical purposes. Fortunately, the technology to produce UHV pressures has been available for decades. Thus, only routine consideration now has to be given to such systems. Detailed information about vacuum systems is available elsewhere.

Surface analytical instruments are almost entirely metal in construction. The metals used must be compatible with the requirements of obtaining UHV pressures, such as a low outgassing rate per unit area, the ability to be heated above room temperature (and in some uses for certain metals to 1000 °C or more), and the capability of
withstanding temperatures near that of liquid nitrogen (78 K), and ease of construction. Stainless steel is used for the main body of most vacuum chambers, as it fulfills these requirements. Some metals, such as brass, have an appreciable vapor pressure in the UHV regime, and therefore cannot be employed for such uses. Mumetal™ can be used also for the main body of a UHV chamber. This is used to reduce magnetic fields in the chamber. With most stainless steel systems some parts are shielded with Mumetal™. This will increase the internal surface area of the system. In addition, the flanges on the various ports of a UHV system are constructed of stainless steel. On these ports are attached the various devices required for a surface analysis system. The flanges, which are almost always circular, have a variety of trade names such as Con-Flat™, Vac-U-Flange™, etc. A circular recess with a knife edge is used to seal flanges with a gasket. Usually the gasket is made of copper, but other soft metals can be used. However, copper is the usual material of choice, as it is relatively inexpensive compared to other soft metals such as gold, and can withstand higher temperatures than indium, for example. For certain special flanges, a soft copper wire is used as the gasket. These special flanges are either rectangular or have diameters larger than the standard sizes. The flanges are held in position with a series of bolts. Almost all of the circular flanges are made in standard sizes and designs. In the USA, the flange size is referred to by the outside diameter; the range of sizes is from 1.33 to 10 in. In areas where the metric system is employed, the size is also determined by the outside diameter. However, in practice the size of the flanges is such that there is almost complete compatibility between flanges manufactured in the USA and those produced using the metric system. This usually permits attaching flanges from different manufacturers to each other. Thus, easy modification to existing systems usually can be made. However, there is a tendency for some manufacturers of surface analysis systems to have only a minimum of extra flanges on their chambers. This reduces the capability of making needed alterations or adding accessories to existing systems when experimental circumstances demand change.

Certain nonmetallic materials are also found in a UHV surface analysis chamber. Electrical feedthroughs (usually on flanges from the outside of the chamber to the interior of the system) require ceramic insulators. Ceramic materials are also used as insulators for wires inside the vacuum chamber, especially when there is the chance of shorting electrical leads. The ability to have liquid cooling for certain components requires special feedthroughs and careful construction. Windows are almost always present on surface analysis systems, so that the specimens can be observed visually and for ease in sample introduction and manipulation. Often small amounts of polymeric material are present in UHV systems. Their most common use is for gaskets on certain valves (e.g. Viton®). This material can be heated to about 150°C without significant outgassing, if it is not under compression. The surface area that these gaskets expose to the vacuum system usually is relatively small compared to the total area in such systems. In addition, polymeric materials such as poly(tetrafluoroethylene) (PTFE) are sometimes used to insulate wires inside a UHV system. Such usage should be kept to a minimum, because these materials will have a high outgassing rate during bakeout (discussed below) of the system. Ceramic tubing or beads are also employed for insulating wires in vacuum systems.

Several different types of vacuum pumps are capable of producing the necessary vacuum for XPS and/or AES spectrometers. Each pumping system has advantages and disadvantages. In many systems combinations of pumps are used either when operating in the UHV environment or in pumping the system down from atmospheric pressure. When it is necessary to bring a vacuum chamber up to atmospheric pressure, a nonreactive, dry gas such as nitrogen is admitted to the analysis system. (If available, the boil-off from liquid nitrogen is a very good source.) This gas should also be free of contaminants such as oil, particulates, etc. For this reason and the possibility of having water present, compressed air should not be used. Ion pumps are used quite extensively for UHV systems with surface analysis capabilities. Electrons produced from cold cathodes (usually titanium) ionize gas molecules. The cathodes and anodes are in a strong magnetic field that increases the electron path length. The positive ions then strike the cathode; this releases neutral Ti atoms that coat the surrounding surfaces. These fresh Ti atoms react with all gases except the inert gases, thus producing the pumping mechanism. Inert gases are buried under succeeding layers of Ti, and the efficiency for pumping these gases is less than with more reactive species. In normal operation the potential between the cathode and anodes ranges from 5000 to 7000 V and currents of a few microamperes. These pumps have a long lifetime, especially when operated in the UHV regime, as the amount of titanium consumed is proportional to the pressure. Common modes of failure with ion pumps are shorting between the cathode and anode assemblies by small flakes of Ti or the build-up of a metal film on internal insulators. Correcting these problems is usually not expensive in terms of replacement parts, but can be difficult because getting to the pump elements usually requires an almost complete dismantling of the spectrometer. If the exposure to inert gases is large, then small amounts of these gases are observed for extended periods even after the source has been removed. In addition, if the pressure in the system is raised, as for sputtering (discussed later) or to react a surface with a

**X-RAY PHOTOELECTRON AND AUGER ELECTRON SPECTROSCOPY**

9
gas, ion pumps will take a long time to recover to the base pressure. The pumping speed for surface analysis systems that use ion pumps is usually about 200 l s^{-1}, but systems with higher pumping speeds are available. Smaller ion pumps are sometimes used to evacuate special regions where the conduction to the main pump of a system is poor. With well-designed ion pumps, the magnetic field does not affect the paths of the ejected photoelectrons or Auger electrons.

Often built into the main ion pump is a separate Ti sublimation pump. This type of pump operates by the deposition of active layers of Ti onto special metal pieces within the vacuum system. These layers are produced by heating Ti filaments for a short time at a low voltage and high current. Until the surface is covered by gas molecules, this type of pump is very effective for removing active gases. In many systems a Ti sublimation filament is set to run with a timer for unattended operation. Titanium sublimation, often at short time intervals, is used during the pump-down of a system when the system pressure is in the 10^{-3} Pa region after it has been taken up to atmospheric pressure. Also, this type of pump is used when sputtering with an inert gas if a turbomolecular pump (discussed below) is not available. In this case, the ion pump usually is turned off. The effective pumping speed of the Ti sublimation pumps can be increased if the surface on which the Ti is deposited is cooled with liquid nitrogen.

An ion pump cannot be operated if the pressure is greater than about 10^{-2} Pa. The time for which these pumps can be used at this pressure should be brief, as extended operation at these pressures will drastically shorten the pump’s lifetime. Evacuation of a chamber from atmospheric pressure to a point at which the ion pump can be turned on has to be done with a roughing pump. One method is the use of a sorption pump, a relatively small, valved vessel that contains molecular sieves. When the sieves are cooled with liquid nitrogen, they can adsorb a large amount of gas relative to their volume due to their large specific area. Sorption pumps can achieve pressures in the 10^{-3} Pa region, but in normal usage the pressure is one to two orders of magnitude higher. If the volume of the system that needs to be evacuated is relatively large, then more than one sorption pump may be required to bring the pressure down to a level at which an ion pump may be started. When the liquid nitrogen is removed from the sorption pump container, the trapped gas will vent to the atmosphere with a simple pressure relief valve or stopper assembly.

The use of a rotary mechanical pump for the initial pump-down of a system is not recommended because the possibility of oil contamination to a UHV system is too large. If such an event happens, repairs to the surface analysis system would be very time-consuming and expensive. An oil trap in the vacuum foreline will reduce this risk, but there are other pumping methods that can achieve the results (i.e. sorption pumps) at about the same cost.

Turbomolecular pumps can be used for surface analysis chambers. These pumps are somewhat similar to turbine engines. A rotating set of blades compresses gas molecules against a set of stationary blades. The gas is then forced to a following set of rotating and stationary blades. This process is repeated several times until the gas is expelled from the turbine area. When operating at full speed the turbines rotate above 20 000 rpm. In order to achieve UHV pressures, the turbomolecular pump is backed with a mechanical pump. For protection of the vacuum system from the oil of the mechanical pump, an oil trap should be installed between the mechanical and turbomolecular pumps. This is especially important in case of a power failure. Some turbomolecular pumps are capable of evacuating a chamber without the use of a separate roughing pump.

Turbomolecular pumps are capable of pumping all gases. However, the pumping speed of lighter gases, such as H\textsubscript{2} and He, is reduced compared to that for higher-molecular-weight species. This type of pump is capable of handling gas loads that are much greater than those of ion pumps. This is especially useful when sputtering or exposing a surface to a gas or gases in a controlled fashion. Cooling of turbomolecular pumps is achieved either with water or air. Care must be taken with these pumps to eliminate vibrations in the analysis chamber. This is especially important when analyzing small areas on a sample. Also, with some pumps, measures may be needed, such as baffles or enclosing the pump, to reduce the high-pitched noise that some of these pumps produce. Turbomolecular pumps require service more often than ion pumps, given equal operation time, and they are available in many sizes. Some systems will have both ion pumps and turbomolecular pumps, so as to take advantage of the strengths of each pump design.

Cryopumps have been employed occasionally in surface analysis chambers, but their use has not been as great as either ion pumps or turbomolecular pumps. These pumps utilize a high-specific-area adsorbent material, usually activated carbon, that has been cooled to a temperature near that of liquid helium. These pumps are vibration free, except for a compressor needed for the helium. This compressor can be away from the main vacuum chamber. Cryopumps have the capacity to adsorb large quantities of gas, e.g. 1000 liters at STP (standard temperature and pressure), and can have very high pumping speeds for most gases. However, when the gas load capacity has been reached, the pump must be warmed to release the adsorbed gas. Provision for this is made so that the evacuated chamber does not have to be exposed to the
released gases via proper valving. By careful operation of the system, and the use of an appropriate roughing pump, the time between warming cycles for a cryopump can be quite long. The ultimate pressure that can be achieved with a cryopumped system is in the $10^{-7} - 10^{-8}$ Pa region.

The venerable oil diffusion pump can achieve the vacuum required for a surface analysis system. However, there are potential problems in the event of failure in the cooling or traps with this type of pump that makes their use questionable, such as pump oil diffusing throughout the vacuum system. Thus, oil diffusion pumps are rarely, if ever, used with surface analysis systems.

Each of these pumps has its own set of strengths and weaknesses. Some suppliers offer a choice of a vacuum pumps for their instruments, whereas others have a fixed design that does not allow any alternatives. For these latter systems, it is usually possible to have modifications made (most easily at the time of construction) to allow for an additional pump. With certain types of applications this can be very important. The cost between the various types of pumping systems is not large. This is especially true when considering the overall cost of a surface analysis system.

Most surface analysis systems provide for heating the various chambers to temperatures of about 150–200 °C. This baking-out of the system results in attaining the base pressure of the system much more quickly than if the system is not heated after it has been brought up to atmospheric pressure. Water vapor is the most usual contaminant in a vacuum system that impedes the achievement of the base pressure. This is true even when a dry gas has been used to vent the system, because there will be a very small residual amount of water present due to some atmospheric gases diffusing into the chamber. Sometimes a vacuum chamber will never reach the lowest pressure that it can attain without being baked out. Most systems are provided with either ovens or insulated blankets that enclose the system. These covers sometimes contain heating elements. In addition, there may be heating elements in the base of the instruments. When baking out a system, certain heat-sensitive components have to be removed, such as micrometer drives, certain electrical connections, etc. Heating tapes that are wrapped around the vacuum chambers can be used. However, as the thermal conductivity of stainless steel is relatively poor for a metal, this method may result in nonuniform heating of the vacuum chamber. This is because it is difficult to wrap a system uniformly with heating tapes. Another approach to baking out a system is the use of a quartz heater placed permanently in the vacuum chamber. This method of heating is not as effective as the use of an oven or heating blankets, but it reduces the need for the removal or protection of components that are heat sensitive and maybe easier and quicker.

### 3.2 Sample Introduction and Handling

Early XPS and AES spectrometers required that most of the vacuum system had to be brought up to atmospheric pressure in order to change samples. Usually the specimens were placed on a carousel or a probe device. With modifications to the carousel it was often possible to handle an irregularly shaped and/or bulky sample. This arrangement also allowed the introduction of several specimens at one time (provided that they were not very bulky). However, much time was lost in re-establishing adequate vacuum conditions for surface analysis on a routine basis. This method is sometimes still used when samples require heating and/or cooling beyond the capability of specimen holders designed for routine use. With some low-cost instruments designed for very routine studies, this approach of venting the main analysis chamber is still followed. However, the design of such instruments should allow only a relatively small volume to be evacuated, and thus the pumpdown time will not be large. Also, the routine operational pressure levels are higher than in most other instruments, and this poses problems with some specimens.

In place of this approach, many manufacturers use a prechamber for the placement of samples onto a holder or holders. This prechamber, often called a loadlock, generally has a small volume that can be evacuated quickly from atmospheric pressure to about $10^{-4}$ Pa. A small turbomolecular pump is usually appropriate for such systems. Then a gate valve is opened, and the sample or samples are transferred into the main chamber. The pressure in the main chamber usually should not rise by more than 1–2 orders of magnitude, and it will then fall to a value close to the original pressure in a matter of minutes. (Note that this presumes that the sample or samples do not outgas excessively.) Also, it is possible to design a glove-box arrangement around the prechamber such that a sample does not have to be exposed to the atmosphere. Other types of sample treatment are possible, such as plasma cleaning and fracturing. To use these types of approaches for specimen treatment successfully, the pressure level in the prechamber should be lower than in a typical introduction system, with relatively short sample introduction times. Sometimes extended pumpdown times will be sufficient to lower the pressure in the loadlock. Another way to overcome this problem is to have a second UHV chamber between the surface analysis system and the atmospheric pressure introduction assembly. Sometimes extremely surface sensitive materials are prepared in this second UHV chamber. A further approach is to have a
monitor is used to locate regions of interest. These areas are wide enough to accommodate wafers 15–20 cm in size, so that larger samples can be studied, thus silicon wafers can be placed on most surface analysis systems at the time of system construction. Some systems have been designed to accommodate very large samples, and larger sample entry ports can be designed for these purposes. However, sample holders can be designed for parts that would allow them to be placed on such holders, due to their size and thickness. Unfortunately, many real-world samples cannot be handled in this manner, and some samples are stored in a computer, and then used to place the wafer in the same spots in the analysis chamber. Unless only a certain size of specimen will always be analyzed, it is prudent to have as much flexibility as possible in the sample introduction chamber and holders.

Samples are placed on a stage so as to allow optimal positioning for the energy analyzer and should also permit visual observation. This is especially important for irregularly shaped samples and/or for analyses where high spatial resolution is required. Positioning should be relatively straightforward and allow movement in all directions. Sometimes this is achieved with motorized micrometers under computer control. For high spatial resolutions XPS and scanning Auger microscopy (SAM; discussed later), a completely eucentric specimen stage (i.e. as the settings for the specimen holder in the apparatus are changed, e.g. the angle, the analysis area is not altered) should be employed, and the ability to rotate and tilt the sample is required.

In addition to having the ability to accommodate samples of irregular geometry and size, sample manipulators should possess several other features if any nonstandard analyses are required. For example, it is sometimes useful to be able to heat or cool samples relative to the ambient temperature of the analysis chamber. Heating can be accomplished by direct or indirect electron bombardment, resistive heating (if the sample is conductive), or with special heating elements on the specimen holder. Heating is useful in certain cases to allow minor contamination to diffuse into the bulk of the sample under investigation or to come to the surface where sputtering can also be investigated. Cooling is needed if a sample has a relatively high vapor pressure, and nonambient temperature processes can also be investigated. Cooling also is needed to bring the temperature down quickly from an elevated level for a heated specimen; this is needed for certain cleaning operations or after exposure to various gas-phase species followed by surface analysis. Cooling also permits the analysis of materials that are solids at room temperature. Heating is usually done with liquid nitrogen, either through flexible tubing connected to a small reservoir, or with flexible braids in the vacuum chamber. With certain designs for a sample holder it is possible to achieve temperatures close to 20 K (using liquid helium). With liquid-nitrogen-cooled systems the temperatures are somewhat above 77 K (the boiling point of liquid nitrogen). Obviously, provisions have to be made to measure the temperature of the sample with a thermocouple. Thus, as wide a temperature range above and below ambient as possible for a sample holder is useful for many analysis situations. The design and construction of sample holders that allow for temperature ranges above and below...
ambient has to be done carefully, otherwise vacuum problems will arise. This usually limits the size and shape of a sample. A manipulator should also have the capability of electrically isolating a sample. This is used to measure the current from an ion gun (discussed later) or an electron beam.

It is essential that the samples to be analyzed are not touched with bare hands or fingers. Disposable plastic gloves (powder free) or lint-free cloth gloves should be always used when handling anything that goes into a UHV system. If the samples have been handled with bare hands and fingers, the specimens need to be cleaned with a solvent or series of solvents. High-purity acetone, isopropyl alcohol and methanol often are used, and an ultrasonic cleaner will speed the cleaning process. Other special sample cleaning methods can also be used. In some instances particular solvents may not be used due to incompatibilities with components in the analysis system. Sample holders and tools used with the samples and sample holders, such as small screwdrivers, tweezers, etc., also have to be cleaned in a similar manner. A laminar flow hood is often used as a workstation for the placement of samples onto holders, and for other operations for equipment that will be placed into a UHV system. Some surface analysis systems are placed in clean rooms to reduce exposure to particulate contaminants. The basic rule to keep in mind is everything that can come into contact with anything that goes in the vacuum system should be as clean as possible. This will help to keep the base pressure in the analytical system as low as possible, and reduce or eliminate analyzing unintended changes to the surface region.

### 3.3 Excitation Sources

As was noted above, the electrons analyzed in XPS are produced by an X-ray source. For most samples Auger electrons are also observed when an X-ray source is used. However, with AES a beam of electrons is most often employed.

#### 3.3.1 X-ray Sources

The most common X-rays used in XPS are the Kα lines from Mg or Al anodes. The anode material is usually a thin coating of the metal on a copper substrate. X-rays are produced when the anode is bombarded by electrons having a potential of about 10–15 kV with respect to the anode. In order to produce a sufficient X-ray flux, the emission current from the electron source filament usually is in the tens of milliamperes range. The filament usually will have a current of several amps. With most X-ray sources a thin window of Al or Be is used to prevent stray electrons from striking the sample and being analyzed.

This will reduce the X-ray flux. Also, adequate cooling of the anode is required, because up to several hundred watts have to be dissipated. Usually a closed-loop pressurized water system is used for cooling purposes. Some systems have filters and ion-exchange beds in the water cooling lines. Inadequate cooling reduces the lifetime of the anode. This can lead to the appearance of ghost peaks due to copper (the anode material, i.e. the Mg or Al becomes too thin). Also, anodes can become oxidized and this sometimes yields oxygen X-rays. The photon energy of the ghost lines is approximately 925 eV and 530 eV for copper and oxygen, respectively. Ghost peaks are usually found for only the most intense lines observed with the regular source. Ghost peaks will also be observed for those lines with binding energies less than the photon energy of the foreign material. Designs where the anode is at ground potential or where the electron filament is at ground potential have been produced. When the latter arrangement is used, adequate precautions have to be made so there is no electrical leakage from the cooling fluid to the rest of the system. Proper safety precautions in both the electronics and cooling systems have to be taken with any X-ray source.

There are several reasons why Mg and Al are the most common X-ray sources used in XPS. The X-ray line width for the combined Kα₁,₂ lines of Mg and Al is about 0.7 and 0.8 eV, respectively. Therefore, the sources using these elements will not excessively broaden or distort most XPS peaks. The Kα₁,₂ lines are actually two closely spaced transitions that are separated by approximately 0.25 and 0.4 eV for Mg and Al, respectively. The Kα₁ line has twice the intensity of the Kα₂ transition. All of the elements that can be observed by XPS have photoelectron peaks that are produced with X-rays when either of these two elements is used as the anode. The kinetic energy of the XPS peaks from either of these sources is such that the IMFP is only about 1–2.5 nm for most elements.

There is not a clear-cut advantage between these anodes for XPS analyses. Whereas Mg has a somewhat narrower X-ray line, a somewhat higher power level can be used with Al. Also, Al sources usually have a longer lifetime. However, there are some systems where there is an overlap of an Auger transition with an XPS line when employing a particular anode. As the kinetic energy of an Auger transition is constant and the kinetic energy of an XPS peak is dependent on the energy of the X-ray source (see Equations (3) and (7)), changing anode materials will resolve the overlap that might be present and make identifying peaks easier in some instances. In order to overcome this potential problem without having a changeover that requires venting the vacuum system, anode designs are produced that have both Mg and Al sources in one assembly. (X-ray sources with four different anodes have been made, but they are not
been observed with sensitive spectrometers. There are other, less intense, satellite peaks that have induced photoelectron peaks with normal X-ray sources. Additional X-ray lines will produce their own X-ray radiation.

Monochromatized X-rays have been observed, such as the Si KL2,3 line. It was noted earlier that the usual Mg or Al X-ray sources have two major X-ray lines, i.e. Kα1,2. In addition, the Kα3,4, satellite peaks appear with intensities of about 10% of the main lines with photon energies about 10 eV higher than the Kα1,2 excited lines. Thus, these small additional X-ray lines will produce their own X-ray induced photoelectron peaks with normal X-ray sources. There are other, less intense, satellite peaks that have been observed with sensitive spectrometers.

In order to overcome this problem, X-ray monochromators for use in XPS spectrometers have been developed. The X-rays produced from the anode irradiate a bent Si crystal as shown in Figure 7. Due to the crystal lattice spacing, X-rays of only one given energy will be reflected, as given by the Bragg equation. Mg cannot be used with a monochromator, as there is no material available that has the proper crystal spacing. However, Al and elements that have a primary X-ray line at an energy greater than Al can be used. It also has been shown that a monochromator used for Al can be utilized also with only slight modifications for Ag as an anode material, because this latter element has a major X-ray line that is almost exactly double the energy of the Al Kα1 line. This approach can be useful in some situations.

3.3.2 Monochromatic X-ray Sources

It was noted earlier that the usual Mg or Al X-ray sources have two major X-ray lines, i.e. Kα1,2. In addition, the Kα3,4, satellite peaks appear with intensities of about 10% of the main lines with photon energies about 10 eV higher than the Kα1,2 excited lines. Thus, these small additional X-ray lines will produce their own X-ray induced photoelectron peaks with normal X-ray sources. There are other, less intense, satellite peaks that have been observed with sensitive spectrometers.

Figure 7 shows the design of the bent crystal arrangement for the production of monochromatic X-rays. (Reproduced with courtesy of Physical Electronics.) The diagram shows the bent crystal arrangement for the production of monochromatic X-rays. (Reproduced with courtesy of Physical Electronics.)

There are both advantages and disadvantages with monochromatic X-ray sources. With only one component to the main X-ray line, namely the Kα1 line for Al, it is possible to obtain sharper XPS peaks in many cases. This allows the resolution of the XPS line shape of an element in more than one elemental state to be obtained more easily than with nonmonochromatic X-ray sources. Vibrational structures have occasionally been found with polymers when an advanced monochromatic Al source has been used. Also, damage to samples that are sensitive to X-ray radiation is reduced greatly with a monochromatic source, but cannot be eliminated for some materials, such as self-assembled monolayers on some metals. Bremsstrahlung radiation that causes a higher background with the normal X-ray sources is absent with monochromatic sources. With certain monochromator designs, with a focused electron beam on the anode, it is possible to irradiate small areas of about 0.15 mm; later improvements have reduced this size to about 0.01 mm longest dimension. Other designs have somewhat larger irradiation areas. Some advanced monochromators also employ several crystals to increase the X-ray intensity on a specimen.

The X-ray intensity that a sample receives with a monochromatic source is much less than that from a normal source. This requires longer data acquisition.
times or advanced electron detection systems to obtain a spectrum in a reasonable amount of time with an adequate signal-to-noise (S/N) ratio. One highly advanced X-ray source uses a rotating anode.\textsuperscript{108} When combined with a focused electron source, very high X-ray fluxes, and therefore large count rates, are produced. The rotating anode is used to reduce the effect of the electron beam being focused continuously on one spot of the anode. This is done to increase anode life and reduce cooling problems. However, this approach requires a very sophisticated mechanical assembly and, as a result, is very costly.

Charging is observed much more often with monochromatic X-ray sources compared to nonmonochromatic sources. With normal X-ray sources the thin film in the assembly between the anode and samples releases secondary electrons because of the X-ray irradiation. This is often sufficient to compensate for the electrons leaving the surface.\textsuperscript{109} However, it has been suggested that the electrons from the thin-film window could cause damage to sensitive samples.\textsuperscript{107} The effect of the K\(\alpha_{3,4}\) lines can be removed with fairly simple computer data-handling routines. These methods have to be used with analyses of the VB region line shapes.\textsuperscript{69,70} In addition, deconvolution procedures have been suggested to remove the K\(\alpha_{2}\) contribution to photopeaks.\textsuperscript{110–112} Some of the results with these methods have been fairly good, but their usefulness in all cases is still questionable. With a focused X-ray beam it has been reported that some peaks shift locally in a non-uniform manner with certain insulators over the irradiated area.\textsuperscript{113}

### 3.3.3 Electron Sources

Auger transitions are observed with X-ray excitation in many XPS spectra (and also by ion beams)\textsuperscript{114} but most AES spectra in surface analysis are produced by electron excitation. The source of the electrons is a heated filament that usually is at 2–10 kV below the sample, which is at ground potential. AES spectra can be obtained if the beam voltage is less than 2 keV, but many of the transitions used for routine analysis will be observed weakly or not at all. There are three types of electron sources available. Many Auger electron spectrometers are equipped with a tungsten filament source that is enclosed in a holder held at a potential of around 30–100 V less than the filament. Then electrons are drawn off through a small hole in the filament assembly. The electron beam is then focused with an Einsel lens arrangement. A simplified diagram of an Einsel lens for a charged particle gun is shown in Figure 8. This design can produce electron beams with a diameter of a few micrometers, and some general purpose systems use electron sources with this design.

The electron beam can be deflected after it passes through the Einsel lens assembly by opposing electric fields; this is done with either plates or segmented cylindrical pieces. As electron beams are easily deflected, spatial resolution of the surface composition of materials by AES was developed soon after the first commercial AES spectrometers became available. Thus, the technique of SAM was developed. The addition of a secondary electron detector permitted images to be obtained using the same principles as those employed in scanning electron microscopy (SEM). Absorbed current images can also be acquired. Borrowing from SEM technology, electron sources with smaller beam diameters became available and this allowed the analysis of even smaller areas.\textsuperscript{115} Eventually, LaB\(_6\) electron sources were developed for use in SAM, offering beam diameters of less than 40 nm with beam voltages of 10 kV. This source has a higher brightness than tungsten filament-based systems. Even smaller beam diameters can be achieved when the beam voltage is raised beyond this value. However, the Auger yield decreases somewhat as the beam voltage increases. A rough rule is that the Auger electron yield is at its maximum when the beam voltage is about three times the transition energy. Thus, even using the highest-energy Auger transitions employed in surface analysis (around 2000–2500 eV), the signal intensity will be decreasing when the beam voltage is raised above 10 kV. As the range of Auger transitions used in surface analysis is from 25 to 2500 eV, there always is a compromise in choosing the beam voltage. Also, it is possible to obtain AES spectra even if the beam voltage is raised to 100 kV.\textsuperscript{116} In addition to raising the beam voltage, electron beam diameters are decreased by lowering the beam current. The beam diameter is proportional approximately to the square of the beam current, i.e. if the beam current is lowered by a factor of four the beam diameter is halved.\textsuperscript{115}

In the early 1990s Shockey barrier filaments were introduced for use with SAM. These filaments consist of a ZrO coating on a single crystal face of tungsten. These sources have two advantages over the LaB\(_6\) filaments. First, useful data can be obtained with beam diameters of around 20 nm. Second, the beam current density is
higher compared to LaB$_6$. Spectra have been obtained with a beam diameter of less than 100 nm even with a beam voltage of 3 kV\textsuperscript{117}. This is not possible with a LaB$_6$ filament. The disadvantage with this source is the need to operate in the 10$^{-8}$ Pa region. Even with a UHV system a special ion pump is placed near the Shockey source. Problems with vacuum systems are less with Auger systems than the typical SEM. Even smaller electron beam diameters can be achieved with field emission sources. However, with these sources there is flicker, i.e. the current varies with time. This obviously will give relative variations in the peak intensities beyond those from the inherent Auger process being investigated. Making estimates of the relative atomic amounts of the detected elements will have greater errors with a field emission source compared to other electron sources. Consequently, the usefulness of this type of electron beam source for AES is reduced greatly.

3.4 Electron Energy Analyzers

After a photoelectron or an Auger electron has been ejected from an atom and has left the solid surface, its characteristic kinetic energy has to be determined for surface analysis. There are only three main designs currently available, with some variations available. Each analyzer has its own set of strong and weak points, especially if both XPS and AES capabilities are present in the same instrument. This is because the requirements for XPS and AES differ when each technique is being performed at its maximum capability. The two major analyzer designs are the concentric hemispherical analyzer (CHA), sometimes called the spherical hemispherical analyzer (SHA), and the cylindrical mirror analyzer (CMA). A third design, the retarding field analyzer (RFA), is a four-grid low-energy electron diffraction (LEED) spectrometer equipped so that AES spectra can be obtained. (LEED is a technique that determines the atomic structure in the near-surface region and is used to study single crystals.) The performance of the RFA for AES is not as good as with either the CHA or the CMA. Many investigators who study single crystals use this type of analyzer for obtaining AES spectra, to check the surface cleaning procedures of their specimens. Also, the additional expense of adding this capability to a LEED system is small. RFA is not used for routine surface analysis, and is not discussed further. Detailed information on this analyzer design is available.\textsuperscript{118}

The CHA has become the analyzer usually used in XPS; however, it also can be employed for AES. The three main parts to the CHA are a retarding and focusing input lens assembly, the hemispheres, and the electron detectors (Figure 9). A few analyzers do not have full hemispheres. Some of the electrons that leave the surface enter the input lens (some systems have a set of lenses) of the analyzer. The lens first focuses the electrons and retards their energy to a relatively low value. This permits much better energy resolution using a reasonably sized analyzer. The input lens also enables the acceptance angle of the analyzer to be changed with variable apertures. With some designs the input angle can be varied to less than 5°. The electrons then pass through an entrance slit into the main part of the analyzer, i.e. the hemispheres. The inner and outer hemispheres have a potential difference applied such that electrons with only small energy differences will reach the other end of the hemispheres. This potential difference then is ramped so that an energy spectrum of the ejected electrons can be recorded. At the end of the analyzer is the electron detection system. Electrons of slightly different energies fall across the exit plane of the CHA. With some electron detection systems this permits a small energy spread of electrons to be analyzed.
simultaneously. This allows for much more rapid data collection, and permits the use of low-intensity excitation sources. Some manufacturers have placed a magnetic lens below the sample holder in XPS systems. The magnetic force lines steer more of the electrons emitted from the surface into the input lens assembly. This increases the signal level, but the magnetic lens cannot be used when making angular resolved measurements, except under certain special operating conditions. A discussion of the electron detection systems is given after CHA and CMA designs have been considered.

Two possible modes of operation with the CHA are possible. One method is known as fixed-analyzer transmission (FAT) or constant-analyzer transmission (CAT). The absolute resolution is independent of the kinetic energy of the incoming electrons in this operational mode, which permits easier quantification of electron spectroscopy data, especially with XPS. The other operational mode involves a fixed retardation ratio (FRR) or constant relative ratio (CRR). Peaks with low kinetic energy (usually found more in AES than XPS) are easier to detect with this method. This is due to the better S/N transmission characteristics in this energy region (up to about 200 eV).

A diagram of a CMA set-up is shown in Figure 10. This design is currently used only with new AES instruments, because the energy resolution is not as good as a CHA for XPS. With some CMAs the energy resolution can be varied, with typical values between 0.3% and 2%. This type of CMA only operates in the FRR mode. As an electron enters the region between the cylinders, it is deflected by a negative potential on the outer cylinder. The inner cylinder is held to ground potential, and the outer cylinder voltage is proportional to the kinetic energy of the electron being detected. Only those electrons that are in a solid-angle cone, usually 42°, with respect to the center axis of the cylinders, will be analyzed. Between the inner and outer cylinders are installed resistively coated ceramic pieces that have a high resistance (usually about 1 MΩ). These ceramic pieces are used so that they will be a uniform potential between the inner and outer cylinders. The effects of fringe fields at the ends of the cylinders are drastically reduced by these ceramic pieces. The sample surface has to be at the focal point of the analyzer, typically about 1 cm from the end of the CMA. This position is usually determined by analyzing the reflected peak at the energy of the incident electron beam. The largest peak intensity should be at this point. If the sample position is off by even a millimeter the signal intensity is reduced. If the beam voltage being used for analysis purposes is higher than the analyzer’s upper energy limit (usually around 3 keV), the beam voltage has to be lowered temporarily to determine the proper sample position.

A variation of the CMA design was used for XPS and AES, starting in the mid-1970s. This analyzer is known as the double-pass CMA and is still used in many laboratories. However, complete analysis systems using this analyzer are not available, but it can be obtained as a component. Although the transmission of the double-pass CMA was good, the energy resolution was poorer than with the CHA for XPS. With a modification to the double-pass CMA it is possible to obtain angular resolved spectra, but not to the small angles usually available with the CHA. Also, the signal strength is greatly reduced in this operational mode. Other analyzer designs are available, but none of them is a part of a complete system. Instead, they are intended as replacements to existing analyzers or are used in custom built, usually research, UHV chambers. One analyzer is an adaptation of a design used for high-resolution electron energy loss spectroscopy (HREELS). Another design is based on a large modification of the CMA, with the electron entrance and exit areas on the side of the main part of the analyzer.

A third analyzer has been designed to be added to a SEM for SAM. This analyzer is a modification of the CHA with less than a 180° deflection in a partial spherical portion design. Usually a SEM is not designed with the vacuum requirements needed for AES. However, modifications often can be made to many existing SEMs that will allow AES capability to be added, but the vacuum level will not be in the UHV region. Sometimes this approach may be less costly than using a regular SAM spectrometer, as the price competition in the SEM market is greater than that for SAMs.

After the electrons are energy analyzed they have to be detected and then the current has to be amplified. This is done with an electron multiplier. The two different types widely used in XPS and AES are the channel-electron multiplier and the position-sensitive detector. The channel-electron multiplier uses metal-coated pieces that have a high potential between them. As electrons strike the cone shaped entrance piece, other electrons are released and directed down the detector. The amplified

![Figure 10](image-url) Cross-sectional diagram of a CMA with the electron gun coaxial; note that some CMAs have the electron gun independent of the analyzer. IC is the inner cylinder, OC is the outer cylinder, EG is the electron gun, and ED is the electron detector.
current is then measured and recorded after passing through the detector. These electron multipliers have a finite lifetime which can be shortened drastically if proper precautions are not taken. The usual failure mode is when too high a signal current is employed for a given multiplier operational voltage. In some systems several of these detectors are placed across the exit region of a CHA. This decreases the time required to obtain a spectrum. However, special procedures and equipment must be used so that gain is uniform for all the detectors.

The position-sensitive detector has the energy-filtered electrons striking a microchannel plate that consists of a series of holes, each having an individual electron multiplier. Then, the amplified signal strikes a resistive anode. At the corners of the anode, connectors are attached to a circuit that measures the amount of charge as a function of position on the anode. This information is then recorded. This type of detector is similar to that used with night vision devices and astronomical detectors. The dynamic range of the position-sensitive detector is not as large as that of the channel-electron multiplier. However, with a CHA the energy range that can be analyzed simultaneously can be greater with a position-sensitive detector. Note that the pass energy (this is related to the amount of retardation incoming electrons experience in the input lens) also plays a role in the energy range of the detected electrons.

The choice of analyzer type is dictated by the expected use. For XPS the CHA, possibly with slight variations, is the analyzer that is employed in most complete commercial systems. This analyzer design is used also by some manufacturers for AES. The CMA is currently available only for dedicated AES systems. Some guidance for the choice of analyzer design can be gained from reported investigations.

Round-robin tests with many different surface analysis systems from various laboratories have been undertaken under the direction of the National Physical Laboratory in the UK as part of the VAMAS program. These studies have centered on the observed signal intensity as a function of kinetic energy with standard samples. The spectra were ratioed with standard data in which instrumental effects were removed. It was found that the instrument function was dependent on the operational conditions, such as pass energy. In addition, the transmission factors sometimes varied markedly with different instruments from the same supplier. Sometimes the shape of the instrument function was similar with analyzers of the same type. It has to be noted that in these studies only instruments with either CHAs or CMAs were used. However, the procedures employed in the standardization studies could be applied to the new analyzer designs. A method to calibrate analyzers has been proposed.

One very important factor is the electron multiplier response. In a study with several instruments it was observed that in some instances the channel-electron multiplier performance changed over time. Any such changes in detector response would make comparisons with spectra taken at different times difficult unless the data were obtained with standard samples at the same time. It has been found that spectral distortion of low kinetic energy peaks can be reduced markedly with a biased screen placed before the electron multiplier. A systematic study on any long-term behavioral differences has not been reported with position-sensitive detectors.

There have been some differences noted in the behavior of CMAs and CHAs when used for AES. The corrected intensity at low kinetic energies, i.e. for about 10–50 eV, decreases somewhat more for the CMA compared to the CHA. Internal scattering appears to be greater with some CMAs compared to CHAs. This phenomenon is thought to be due to higher-energy electrons than those being energy analyzed hitting the outer cylinder or sphere and then being directed to the electron multiplier assembly. This results in a higher baseline signal, and therefore more noise in a spectrum. Field trimmers and the exit apertures have been identified as other sources for scattering with a CMA. With an individual CMA this effect was very pronounced; it was suggested that extended sputtering might have been the cause of this observation.

3.5 Small Area Analysis

The analysis of small areas by XPS and AES has already been mentioned. The approaches used in XPS and AES for this type of analysis are very different. Spatial resolution is defined as the distance between two signal levels over a sharp feature, such as a knife-edge. The electron microscopy community uses the distance between 80% and 20% of the observed signal, but no firm definition is used by the electron spectroscopy community for elemental spatial resolution. However, when profiling (discussed later), depth resolution is usually taken as the distance between 84% and 16% of the signal change (this is two standard deviations). The difference in spatial resolution between the two definitions is about 50%. The electron microscopy definition (based on a secondary electron image) is much less dependent on the material being analyzed. Several methods are used to analyze small areas by XPS, whereas with AES the strategy employed is to decrease the size of the electron beam. Also, it is necessary to distinguish between point analysis and imaging. Point analysis is investigating a single area of a small dimension with a suitable measurement approach or with a specially designed electron analyzer. These analyses can be either a survey type spectrum or
detectors have reduced the analysis size to about 20 μm in diameter. Further improvements in X-ray sources and apertures in the input lens of CHAs. This technique measuring a photoelectron peak intensity.

The analysis of areas of less than a few square millimeters commenced in the early 1980s with XPS, using a small-diameter electron beam to excite X-rays. Also, the X-ray shape can be made to be nearly rectangular to various dimensions. The area of irradiation from the X-ray source is found by a phosphor or an X-ray-sensitive film that changes color and is observed with a microscope or a television monitor display. The photoelectron signal strength is very sensitive to the distance between the specimen and the input lens of the electron energy analyzer similar to that when using a CMA, as indicated above. This requires a method to measure quickly a photoelectron signal from an element thought to be present on the sample surface. In addition, that element should give a strong signal. In usual practice the focal point of the microscope or television camera can be used routinely, with only occasional checks being required by measuring a photoelectron peak intensity.

Somewhat later another method was developed for small area analysis by XPS with the placement of apertures in the input lens of CHAs. This technique initially permitted the analysis of areas of about 0.25 mm in diameter. Further improvements in X-ray sources and detectors have reduced the analysis size to about 20 μm in diameter. The area of analysis is identified by different strategies. In one approach the signal from a metal dot (often gold) is maximized, and this location is calibrated with a television monitor. Note that the metal dot has to have dimensions that are close to that of the analyzer spatial resolution. The metals used have a high relative XPS sensitivity. With systems that have an electron gun for AES, the secondary electron image is employed to locate the analysis area.

XPS imaging has been developed and several different approaches have been used. Before elemental images are recorded, the usual experimental procedure is to record a survey spectrum that determines the elements and possibly different chemical states to be imaged. One method has been to use an X-ray line source to obtain a spectrum over several electron volts and then move the sample. This approach requires the use of a position-sensitive electron multiplier. The spatial resolution obtained with this technique is limited to that of the X-ray source and possible errors in moving the sample stage. Also, it is a time-consuming procedure. Having a spectrum over an energy range can detect changes in the chemical state of the element being analyzed on a routine basis.

A more widely used technique involves refinements in the input lens of CHAs. At the entrance to the input lens there are deflection plates (see Figure 9) that only allow electrons emitted from a small area to enter the assembly. To use this approach an area larger than the imaged area has to be irradiated with X-rays. The electrons to be imaged are then magnified and passed through an aperture where deceleration occurs before entrance into the main part of the CHA. The electrons are then detected with either a series of channel electron multipliers or a position-sensitive detector. The signal intensity is then measured as the peak energy maximum minus a baseline value a few electron volts away from the peak. An image is produced by rastering the deflection plates over the field of view of the analyzer. With this approach the spatial resolution is of the order of 30 μm. It is also possible to obtain an entire survey spectrum or detailed elemental spectra at one setting of the deflection plates with the same spatial resolution as the image.

A modification to this approach has been developed and is illustrated in Figure 11 in a change to the design of a CHA. In this approach, imaged electrons enter the spheres of the CHA. However, after travelling a short distance in the main part of the hemispheres, they enter another analyzer called a spherical mirror analyzer that is on top of the main CHA. The electrons are then directed back to a point near the exit area of the main CHA. Finally, the imaged electrons are focused on to a position-sensitive electron multiplier that produces an image that is usually recorded with a video monitor. Then the image data is digitized. Spatial resolution of less than 5 μm have been achieved with this approach. However, it must be remembered that this is an image and other methods have to be used for analyzing a small region. With this analyzer it is possible to perform regular XPS analyses, as a series of channel-electron multipliers is placed alongside the position-sensitive detector.

An entirely different technique is used by one manufacturer. Again, an area larger than that of interest is irradiated by X-rays. The electrons from the entire acceptance area of the analyzer pass into the input lens of a CHA. In two stages the electron image is magnified by about a factor of 16. Then the image is focused onto the entrance area of the main part of the CHA. This method makes use of the fact that if the distance from the image plane is the same as focal length of the lens, all of the electrons have a common intersection point on the center line of the lens. This process has been described in terms of a Fourier transform, in this case converting spatial information into angular information. The electrons of one energy then are focused at the exit area of the CHA. The electrons then pass through a hole where they enter another lens assembly where the image is reconstituted in the reverse fashion, i.e. angular information is
Figure 11 The cross-sectional diagram for an imaging CHA used for XPS. The analyzer uses a position-sensitive detector for images and channel-electron multipliers for regular XPS analyses. MCP, multichannel plate. (This figure (modified slightly) is reproduced with courtesy of Kratos Analytical Instruments.)

transformed into spatial information. The electrons are detected with a position-sensitive detector in a similar fashion to that mentioned above. Spatial resolutions of less than 5 μm have been achieved with this approach. With this analyzer it is possible to perform regular XPS analyses, as a series of channel-electron multipliers is placed at the exit plane of the CHA that is alongside the final electron lens assembly.

With the last three approaches discussed it is possible to obtain line scan data after the image has been recorded. With digital recording of the data a line can be connected between any two pixels. Those systems that use an X-ray line source, of course, produce a line scan directly.

Another method has been developed to obtain both high spatial resolution and images in XPS. The focused X-ray source using a monochromator has been designed so that the electron beam is rastered across the anode. This allows an image to be produced, and the spatial resolution is claimed to be about 10 μm. Also, the input lens region of the CHA is designed specifically to accept the spatially generated electrons. The area of analysis can be identified in two ways. First, a video display is used to identify the locations of interest while the sample is in the introduction system. Then, the coordinates of the locations of interest are stored in the system computer. The specimen then is transferred to the main vacuum chamber, and the sample is positioned for analysis. A second method can be employed also. A secondary electron image from the X-ray source is used to locate desired locations on the sample. The instrument also has a very unique configuration, but how adaptable the design is for a wide range of specimens is questionable, as it was designed primarily for large silicon wafers. Also, the ability to modify the instrument appears to be very limited. A review of this topic is available.  

With AES the spatial resolution is primarily a function of the electron beam diameter. However, there are other factors that have to be considered. When an electron beam bombards a solid surface, some of the electrons will be deflected from the point where they strike the surface. In addition, other electrons that have penetrated into the bulk can be scattered back toward the surface region; these electrons are called backscattered electrons. If these electrons have sufficient energy they can create Auger electrons that will be detected. Also, X-rays created by the electron bombardment will produce some detected Auger electrons. This effect becomes more significant at higher electron beam voltages, such as 10 keV or above. These effects will cause a broad, fairly weak background away from the point where the electron beam strikes the surface. Calculations have shown that this is not a large effect, but it is more important with higher-Z elements.

Topography also can degrade spatial resolution in SAM, and this effect is illustrated in Figure 12. Here, as the electron beam strikes the edge of a feature, some electrons will exit the material and further bombard the surface away from the point of intersection. Again, if these electrons have sufficient energy, Auger electrons will be produced, and this will degrade the spatial resolution. This has also been observed with small Al and Al₂O₃ particles on Si.

3.6 Data Collection and Handling
The electron multiplier signal must be further processed before useful information concerning the surface composition can be obtained. With the earlier spectrometers used for XPS and AES the signals were detected either by pulse counting with a rate meter or by analog methods, depending on the current levels. The output then
was displayed with an ink on paper recorder. However, in most systems these approaches gave way to small computers for data collection and processing. As with practically all current advanced scientific equipment, a computer is now used almost exclusively for system operation in AES and XPS. With many advanced instruments the computer hardware and software systems are very sophisticated.

The primary computer use is in the operation of the basic electronics, i.e. the electron energy analyzer control and simple data collection. The computer provides a voltage via a digital to analog (D/A) converter to operate the ramp electronics for the electron energy analyzer. The voltage produced by the D/A usually will have a small range, such as 0–10 V. This voltage is then amplified by the analyzer control electronics to the level required by the energy analyzer. The D/A has to have sufficient resolution so that the energy resolution of the electron analyzer is not compromised. For example, a 16-bit D/A can produce a resolution of one part in 65,563 over its output range. If it is desired to analyze the kinetic energy of electrons over the range 0–3200 eV, then the smallest energy difference that could be sampled would be just under 0.05 eV. This, of course, assumes that there are no other sources of error in the electronics (e.g. drift) and analyzer systems. It has been determined that an error in just one D/A channel can affect a peak’s energy resolution and shape.\(^{139}\)

The kinetic energy range 0–3200 eV is typical of many analyzers, as it covers the span for most AES and XPS transitions used in surface analysis. Note also that an exact difference between points of 0.10 eV separation, for example, is not possible. The situation is much more complex if the photoelectrons or Auger electrons are retarded before entering the main part of the energy analyzer. However, this does permit even increments, such as 0.1 eV. This provides some analyzers with the capability of measuring electron kinetic energies to values beyond 4000 eV. The computer will also provide the voltage dwell time at each step.

The signal from the electron multiplier then is stored in computer memory or a disk drive. With systems that employ a lock-in amplifier (used to display derivative AES data) or a rate meter, the output voltage has to be fed into an analog to digital (A/D) converter. This device converts an analog signal, such as a time-varying continuous voltage, into digital information that is stored by the computer. At each energy interval, a separate electron intensity will be recorded. The computer can repeat energy sweeps and sum them to improve the S/N of the spectrum. It is also possible to record spectra over narrow energy regions sequentially or serially. The former approach can be used if it is suspected that sample degradation due to the X-ray source or electron beam is damaging the specimen under investigation. The low levels encountered when pulse-counting techniques are used can be treated in a more direct fashion. Each individual pulse can be detected by counting circuitry, which then transfers the total count after a preset time to the computer. Such an approach must be used with position-sensitive detectors or analyzers that have several channel-electron multipliers because multiple signals are being detected and processed simultaneously. With signal levels up to several million counts per second, pulse counting can be employed. With count rates above this value the counting circuits are not able to function properly, as one pulse cannot be processed before the next one arrives. When this happens the signal has to be converted into the frequency domain for signal processing.\(^{140}\)

Many of the operational settings on AES and XPS spectrometers can also be placed under computer control, such as resolution control of the analyzer and the various potentials needed for the input lenses on a CHA, the X-ray power in XPS, the electron gun settings in AES, and the voltages needed for the electron multipliers. The control of accessories, such as ion gun operation, can be placed under computer command. This allows for either continuous (if not prohibited due to other experimental conditions) or interrupted depth profiles. With certain systems the sample manipulator can be under computer control so that different samples or locations on the same specimen can be analyzed in succession without operator intervention. Angularly resolved determinations also could be made in this manner. System checks can be monitored with a computer. In the event of a failure in some part of the instrument, system diagnostics may be incorporated in the operational software to help pinpoint the problem.

Sputtering can be controlled with a system computer. This is very useful for profiles and a good profile routine

![Diagram](image-url)
will permit the ion gun timing to be varied as the experiment proceeds. Selected elemental regions can then be analyzed, displayed, and stored during a profile. This is especially useful when the composition is changing rapidly as a result of small sputtering times. This may then be followed by regions where the composition varies little. In this situation there is no need to have small time intervals between sputter cycles, as can occur with a thin oxide layer or at the interface of layered materials.

Another approach to find elemental depth distributions is to create a slight gradient across a specimen. Then line scans using SAM are made for the elements of interest. Ball cratering is one of the methods used to produce the gradient.\(^{(141)}\)

Computers can do much more than just collect a spectrum and then display and store it. The storage of necessary experimental information, such as system pressure, electron multiplier settings, operator, date, and some sample identification should be included in the recorded data. The ability to scan only those regions of interest and to enhance low-level signals or take spectra at high resolution compared to survey experiments are additional advantages. Also, there is a reduction in the time required for an operator to be involved directly with all of the data collection procedures. Extended or even overnight data collection can be made routine. With the continuing rapid increase in computer capability and reduced costs, even more power will be available in the future. Real time displays of the experimental results, even with some data reduction (e.g. approximate intensities from profiles or images), are usually available with most systems.

After the spectrum has been recorded and stored by the computer it has to be displayed in order to make use of the collected information. Spectra initially are shown on a monitor for visual inspection by an instrument operator. Permanent plots can be obtained on output devices which often have color capabilities to enhance the display and clarify the observations. Spectra can also be archived on magnetic tapes or magnetic disks. High-speed computer systems having adequate memory offer the ability to collect data while processing previously acquired results.

Advanced data reduction routines are available with most current XPS and AES instruments. In addition, there are several independent data handing programs that can be procured for XPS and AES, providing capabilities that the instrument programs lack.

The display of only a small region of a spectrum often is useful and this feature is found in most programs. Occasionally a point will be quite far removed from its neighbors due to a noise spike or some other temporary instrument malfunction, and its repositioning can be easily accomplished without jeopardizing the value of the experiment. The ability to overlay two or more spectra, or to subtract one spectrum from another for comparative purposes, is usually available. Adding a fixed quantity to each point in a spectrum has advantages for certain display situations. Mathematical smoothing of a spectrum is readily accomplished.\(^{(142–146)}\) The derivative of a spectrum is often computed, usually for rapid visual examination of AES spectra, even if the data has been collected in the undifferentiated mode. It has also been suggested that the second derivative of XPS spectra can indicate the presence of more than one component in what appears to be the envelope of a single peak.\(^{(149)}\) As noted earlier, procedures utilizing deconvolution methods have been suggested as an alternative to the use of a monochromatic X-ray source.\(^{(110–112)}\) Many find the ability to annotate a spectrum before making a hard copy to be useful, especially for reports or presentations.

Most of the above procedures are displayed on the computer monitor. However, some data-handling procedures do have drawbacks. For example, if smoothing is done over too wide a region (i.e. the number of points chosen for the smoothing algorithm is about the same as the total number of points defining the peak), some minor features will probably be lost. Also, smoothing is for visual purposes only, as no additional information is inherently available after smoothing. There are several different ways in which a derivative can be obtained mathematically, and each method has its own set of advantages and disadvantages.\(^{(150)}\) The exact correction of a data point due to a spike is arbitrary.

Semiquantitative analysis from XPS or AES spectra is a data reduction procedure available with most software provided with commercially available instruments. However, the use of these programs requires much understanding and care. The accuracy of some methods has been questioned, and it has been suggested that the results could sometimes have an accuracy of no better than 50%. As a simple example of the potential pitfalls with both XPS and AES, it has to be recalled that the IMFP of the ejected electrons depends in part on the kinetic energy of the transition being analyzed. Therefore, a different volume will be analyzed for each element in the surface region for many materials. However, in many instances even a relatively poor estimate of the surface composition is of use for many problems.

In XPS the usual method for quantitative analysis is to determine the area of each photoelectron peak. A much less used approach is to measure the peak height of selected transitions.\(^{(151)}\) This latter method usually is done manually, but it can be used as a rough indication of the composition of the surface region. The database used by Wagner et al.\(^{(151)}\) was built with instruments that are no longer available commercially. In order to use this approach with most spectrometers, a restandardization would be required. Also, this method would yield poor
results if there is more than one chemical state present for an element in the analysis volume. Usually the most intense peak of each element being analyzed is used in either procedure, unless there is a strong reason not to do so. Before the area of a peak can be determined, a baseline has to be established. There are several methods can be used. The background intensity is due to photoelectrons and Auger electrons from the bulk that have lost some energy due to inelastic collisions before going into the vacuum phase. As such they will have a broad energy distribution. The simplest procedure is to select a point on either side of the peak being analyzed and assume that a straight line (defined by these two points) will represent the baseline for the peak. It also is possible to use a few points on either side of the peak to determine the baseline. This method will work, at least on a level that is visually satisfying for many peaks. However, this process cannot be employed for many of the major peaks with the transition metals, as they have significant losses in the immediate energy region of the photoelectrons. Another popular baseline selection procedure is the so-called Shirley method. This approach subtracts a proportional quantity of the signal at higher binding energies times the intensity at a point below the peak from the experimental data. This yields a baseline-removed spectrum with the same intensity at both end-points. Empirical methods such as parabolic functions on the high binding energy side of a line or a tail function are sometimes employed. Several other theoretical techniques have been used. Tougaard has investigated this problem theoretically and has developed relationships to model the background. He has also found an empirical equation that closely follows the more complex theoretical expressions and which is relatively easy to implement. Many commercial data analysis programs now include this empirical expression. However, proper use of this empirical method requires that the data have to be acquired at least 40–50 eV below the peak of interest. This topic has been reviewed in detail elsewhere.

Of the several ways to determine the area of a peak, the simplest is to simply integrate the peaks under the curve after baseline subtraction. However, most approaches involve fitting the curve to a function using a minimization procedure, such as nonlinear least-squares or the Simplex approach. One of the simplest curves used is the Gaussian, which is defined by three separate parameters: peak height, width, and position of maximum intensity. This is a useful approximation with peaks that are fairly broad. However, if the spectrum has been taken with good energy resolution and the peak is inherently narrow, the Gaussian representation is not an adequate fit of the experimental curve. This is because the natural line shape has Lorentz components due to the X-ray source and the electron emission processes. The Lorentz function has the same three parameters as the Gaussian function, but it has broader wings. This is also found with some relatively broad peaks, which are better described with the Lorentz line shape. Some programs allow for the calculated curve to be represented by a combined Gaussian–Lorentzian function. The fraction for the Lorentzian or Gaussian contribution is fixed or can be a variable, depending on the program. These curve-fitting programs can take into account the presence of more than one component in a complex spectrum envelope. In addition, often it is possible to fix or limit the range of the energy separation between two peaks if this quantity is known, as with doublets. The same can be done for area ratios of doublets; for example, p_{3/2} peaks have twice the intensity of p_{1/2} peaks, but the baseline subtraction routines may introduce some errors that would make fitting the exact ratio difficult. Care should be used when using such constraints, because the fits should usually come close without restraints. The computed areas then are normalized with the use of sensitivity factors computed by Scofield. These theoretical cross-sections have agreed well with experimental results in comparative studies. The Scofield cross-sections also have coincided reasonably well with other calculations. With many instruments the transmission factor and electron detector response as a function of kinetic energy for the analyzed electrons must also be taken into account in computing the relative areas under the photoelectron peaks. When the relative areas of all the curves for the detected elements have been determined, an elemental composition of the surface region can be calculated. From the results of curve fitting the full-width at half-maxima and peak heights are computed. These results can be used for comparative purposes with other studies.

Some shortcomings in the above methods can be encountered in commercial software. First, the choice of baseline model is often done with one of the simple approaches, and this has been suggested as a source for large errors in some cases. Second, even a combined Gaussian–Lorentzian curve often cannot correctly depict some narrow XPS peaks. The Doniach–Sunjic line shape can better describe the asymmetry experienced with many metals, arising from electron–hole interactions. However, this line shape is not usually included in curve-fitting programs, and empirical asymmetry equations often are employed to take this effect into account. With some high-resolution studies of polymers, peak asymmetry has been detected due to vibrational effects. Third, angular effects have to be considered when employing the theoretical cross-sections. When s-level peaks are being analyzed, a correction due to the electron ejection angle is not
needed. However, when other energy levels are being analyzed (i.e. p, d, and f), appropriate corrections should be made.\(^{(161)}\) This assumes that the surface is flat, which is rarely true. By the proper choice of angle between the sample surface and the energy analyzer, a correction is not required. Many instruments are constructed with this ‘magic angle’ at about 56°. Also, for most analyzers there is a finite angular width so that any correction will be an approximation. Quite often this effect is neglected with typical specimens. Also, consideration has to be taken of shake-up effects when trying to measure the relative intensity of an XPS peak. As can be seen from this discussion, the correct determination of the area of an XPS peak is complex, and often many of these factors are not included in fitting programs. Other factors, such as detector response, X-ray intensity, and elemental density within the specimen must also be considered. Some of these values will tend to cancel out when making relative measurements, which is the most common method used.

Unfortunately, much the same can be said regarding the use of AES spectra for quantitative analysis purposes. There are many different approaches that can be used for quantitative AES. Many of the currently available procedures included with most commercial software usually employ only the simplest approaches. These methods include the use of peak-to-peak heights or the negative excursion in a derivative spectrum, and the peak height of an N(E) (number of electrons that are detected at a given energy, i.e. on the horizontal axes of Figures 5 and 6) AES spectrum. Comparisons between the spectrum of interest and published data made under standard conditions (the most important experimental variable is the electron beam voltage using this method) are then made. This is sometimes done with analyzers, such as a CMA of the same basic design, but not with the specific model. It has to be remembered that these methods use only a few points in a spectrum. All of these simple methods suffer from the fact that changes in the chemical state between the standard used and the material under investigation may significantly change the response between the two different elemental environments. There are numerous examples where the peaks will be at different energies between two chemical states for the same element (see Figure 6). Also, such approaches cannot be used if the signal results from two elements that overlap, as with Ti and N.

More advanced procedures have been used to obtain quantitative AES information and some of them are available in commercial software. These include the use of linear least-squares,\(^{(162)}\) principal component analysis,\(^{(163)}\) and factor analysis.\(^{(164)}\) This latter approach has uncovered unexpected components or sputter effects in depth profiles in some systems. Some of these more sophisticated methods have also been used in XPS,\(^{(165,166)}\) With these procedures a much wider spectral range is used. Thus, because the statistics are better, results based on using these approaches should be better than those employing the more simple methods. However, greater effort is required in the use of these methods in terms of analyst time and experience. Also, the data quality has to be relatively good, or the results may not have much meaning.\(^{(167)}\) In some cases, improved results are obtained when the effects due to primary and secondary electrons are considered.

Matrix effects, backscattering, Auger transition probability, and IMFP should be considered also.\(^{(168)}\) In some instances these effects are not important. The ability to have user-supplied standards that are more nearly representative for the problem at hand reduces some of the most glaring problems in the use of any analytical procedure with AES. The use of AES and XPS for quantitative purposes has been reviewed thoroughly elsewhere.\(^{(169,170)}\)

Most image data collection methods involve using two data points, i.e. a point at the top of an elemental peak and another on the baseline at least several electron volts away on the higher-kinetic-energy side. The difference is then calculated to give a peak intensity. Three points can also be used, with the third point being at a lower energy than the peak maximum. Then a line is calculated between the first and third points to give a baseline, and the intensity is computed from the peak maximum to the baseline at that kinetic energy. The reason for employing so few points is that images require a large amount of computer memory and calculations. For example, with a 256 by 256 point image, the number of peak maxima points alone will be over 65,000.

A wide variety of procedures is available to process images from either XPS or AES digital elemental maps and secondary electron micrographs. Many of these routines are included in system software, but specialized programs can be purchased that can extend this approach. As computer capability increases, even more sophisticated image analysis will be possible. Various filters are used to enhance the quality of the images. The choice of the particular filter depends on the type of features in a given image and operator choice. The use of color images, with each element having a different color, gives an easily visualized distribution picture. For example, this is useful to picture the distribution of a catalyst on a support, a contaminant on a silicon wafer, or the wear area on a lubricated surface. It is also possible to use color to see gradations in the intensity of an element over the imaged area. Occasionally, these processed images can mislead an analyst and other factors that contribute to the signal must be considered. This was shown in the work of Prutton and co-workers in a study using Auger images of overlayers on various substrates.\(^{(171)}\) Different image analysis approaches can
yield inconsistent findings.\textsuperscript{172} There have some attempts to quantify data from images, but the task is difficult, as reviewed elsewhere.\textsuperscript{173} Data from line scans also can be treated in the same fashion as images. With specimens that have pattern samples with regular features, line scans will produce the same information in a much shorter time. This is especially true with SAM. With either approach weak signals will often be missed. Much of the original effort in image analysis came from work on the pictures obtained with the deep-space probes.

The semiquantitative data analysis procedures used in AES and XPS depth profiles usually employ the simpler methods, such as simple peak areas or peak heights. Some data collection routines, especially with AES, will collect only two or three points per element per sputter cycle. However, it is better to collect the data over an energy range that encompasses the elements being analyzed. This will allow more points to be used, even if a simple area determination is made. In addition, this permits some of the more detailed procedures, e.g. factor analysis, to be employed if the need arises.

There are a number of other factors that are important in the software that is available for the collection and further treatment of AES and XPS data. The most advanced systems have programs that are easier to use than their predecessors. This relieves the operator from needing a detailed knowledge about the program, and is useful if there are a number of occasional users. However, although this frees the operator from an extensive learning process, just to get started, if there are some subtle operational or computational effects that influence the data and subsequent analysis, they could be easily missed.

The original program source code is usually not provided. This prevents an individual from introducing errors into the operational program for an instrument, which could have disastrous effects. On the downside, improved methods of data collection and treatment cannot be introduced by an advanced analyst and require waiting for updates from the instrument supplier. Also, errors in the data-treatment programs cannot be uncovered and corrected.

The ability to transport the data away from the original program usually is provided. Thus, in some instances the ability to use procedures other than those supplied with an instrument is possible. However this usually requires either some programming effort by an operator, or software from a third-party supplier. A VAMAS standard format is now available for data transfer.\textsuperscript{174} This allows further treatment with other programs in a specific manner suitable for a given laboratory, and could include spreadsheets, word processor programs, special plotting devices, databases, and third party data reduction programs.

4 ACCESSORIES

4.1 Ion Guns

Most surface analysis systems are purchased with an ion gun as an accessory, and it has two main uses. It operates by striking the surface with energetic ions (usually from an inert gas with energies of a few hundred to a few thousand electronvolts) in order to sputter, i.e. remove atoms from the surface. The first use is to clean a surface of the almost inevitable contamination layer present on a sample. With many analysis systems this can be done within a few seconds for most specimens. The other use is to obtain a depth profile of a sample by either XPS or AES. This is useful in determining the thickness and composition of a layer that has been formed by some process, such as an oxide layer formed on a corrosion specimen or a sample from a deposition procedure. Another example is to study a material that has been implanted with highly energetic ions to change a material’s physical or chemical properties.

It is possible to analyze the species that are removed from the surface. The most common method of analysis of the sputtered species is by secondary ionization mass spectrometry (SIMS). This capability is available on many XPS or AES systems, but much of the work with SIMS is done on instruments designed solely for this method of analysis.\textsuperscript{175–177}

There are two main types of ion guns. The more common design is founded primarily in the Einsel lens approach. The main components are an inlet valve, ionization, acceleration, focusing, and deflection regions. The gas is usually admitted from a small reservoir with a variable leak valve. With small compressed-gas cylinders care has to be taken so that impurities are not introduced. There is a maximum pressure that can be employed with variable leak valves. With a variable leak valve the amount of gas being admitted into the ion gun can be finely adjusted. Some systems have variable leak valves that are thermally controlled, which eliminates operator control for fine adjustments in order to maintain a constant pressure of the bombarding gas. The pressure is measured by the system ion gauge or by the ion current in the ionization assembly of the ion gun.

A heated filament boils off electrons that are attracted by a positive potential, usually about 70 V, in an ionization chamber containing the sputtering gas. The newly created positive ions are accelerated to the desired sputtering energy by a voltage placed on the ionization chamber with respect to earth. These ions then are focused in the Einsel lens part of the ion gun. Most ion guns have deflection plates that steer the beam after the ions have passed through the Einsel lens. It has been suggested that the sputtered area should be at least 10 times the area being
analyzed. This is because the ion beam, which is about 0.1–1.0 mm wide, with a well-designed ion gun, has a Gaussian distribution which gives rise to edge effects. The crater produced by the ion beam therefore has a depth gradient, whereas ideally it would be flat bottomed. If only a small area is being analyzed, this would not present much of a problem (typically in single-spot AES the analyses are a few square micrometers in area). This assumes that the ion gun is focused on the same area that is being analyzed. However, as the area of analysis in XPS is almost always much larger than with AES, the sputtered area must be correspondingly much greater. It is better to raster the ion beam, rather than defocus it, because with a defocused beam the edge effects of the crater will be larger. The same reasons apply if an AES analysis is performed by rastering the electron beam or if different locations on a sample are being studied simultaneously. It is also possible to use a defocused ion beam and then analyze the broad crater edge with SAM to study compositional differences as a function of depth.

Most ion guns operate in a dynamic or differentially pumped mode, i.e. the source gas is continuously being admitted into the ionization source. With this approach the ionization chamber of the ion gun is usually evacuated with a separate pump, most often a small turbomolecular pump. This permits the ion source to be at a few orders of magnitude higher pressure than the main analysis chamber, that also is being continuously pumped. There will be a pressure rise in the analysis chamber, but this is usually only about 1–2 orders of magnitude over the base pressure. With a vacuum system that uses ion pumps, residual sputtering gas will remain, even after the gas source is turned off. This is due to the memory effect with ion pumps, and is much more pronounced with inert gases.

Ion guns usually operate with a current density of a few tens of μA cm⁻² and an acceleration voltage of 2–5 kV. For many materials this current density results in a removal rate of 5–10 nm min⁻¹ or more, which in many instances is too large. The sputter rate can be reduced in several ways. The pressure in the ionization chamber can be reduced, but this requires adjustments with the variable leak valve. Another way is to lower the ionization filament current. Also, the sputtering rate can be reduced by rastering the ion beam over a larger area than is needed to produce a crater consistent with the technique that is being used. The sputter rate also can be lessened by using ions with lower kinetic energy, such as a few hundred electronvolts. Relative sputtering rates can be measured with standard materials, such as a known thickness of an oxide layer on Si or Ta, or with a standard sandwich material of Ni and Cr.

Another ion gun design, called the dualplasmatron, has two ionization regions for the ion production, and can operate over a wide range of ion currents. Thus, very low to very high sputter rates can be used as required by a particular analysis. However, this type of ion gun is much more expensive than conventional designs. When sputtering to depths of more than about 1 μm, AES or XPS are not the usual methods used; dynamic SIMS would probably be a better choice of technique in these instances.

Sputtering is a destructive process. Even with the removal of surface contaminants the surface will be altered by disturbing surface crystallinity or changing the chemistry of the surface species. For example, the reduction of many metal oxides has been observed with sputtering. In addition, each element has a different sputtering rate, and occasionally the same element in different oxidation states has a distinct sputtering rate. These effects, along with such factors as topography and radiation-enhanced diffusion can affect the depth resolution of profiles. Several approaches can be taken to reduce these difficulties, such as lowering the ion beam voltage and using a heavier sputtering gas (Xe instead of Ar). Other methods require changes in the sample manipulator or analysis chamber design, for instance a glancing ion beam angle, the use of two ion guns striking the sample at different angles, or sample rotation. With this last procedure the specimen is slowly rotated (about 1 rpm) during sputtering. With some samples under ideal conditions, depth resolution of the order of 2–3 atomic layers may be possible.

### 4.2 Flood Gun

Earlier, the problem of charging in XPS was discussed. An electron flood gun often is employed to help overcome charging. For use in charge compensation the voltage and current of the beam should be adjustable from above zero for both parameters. The production of electrons requires a potential of tens of volts for extraction purposes. This means that a deceleration assembly is required for the low voltages needed for a flood gun, and the beam is diffuse. There will be added complications with systems that have magnetic lenses. In these instances a heated filament will be used, but some acceleration potential still will be required.

### 4.3 Fracture Stage

For certain materials-science studies a fracture stage is a useful accessory. This permits a fresh surface to be analyzed without sputter-induced changes. The bulk composition of a sample can be determined by surface analysis methods in this fashion. With SAM for example, the composition of grain boundaries can be compared to that of the main crystallite. Also, such a fresh surface can be...
exposed to study the initial stages of reactions with a reactive gas, such as oxygen or water. The material to be fractured is held in a special sample holder, and most specimens are cooled well below room temperature with liquid nitrogen. The sample, often notched, then is fractured with an internal hammer assembly. The specimen holder then is transferred to the sample stage for subsequent analysis. Most samples require machining before they can be placed into the special fracture specimen holders. The fracture stage usually has to be on its own vacuum flange and should be in the analysis chamber.

4.4 Special Auxiliary Chambers

As noted above many surface analysis systems use a loadlock for sample entry into the analysis chamber. More specialized systems can be used, but these are usually custom-designed features. Glove boxes can be constructed around the loadlock for atmosphere-sensitive materials. A temporary and inexpensive alternative, but with some obvious performance degradation, is a portable glove bag. Another possible method is to store sensitive materials in a portable transfer assembly that has UHV flanges and appropriate transfer capability. Such an assembly then can be attached to a loadlock for subsequent evacuation. For certain materials preparation applications that require UHV, such as molecular beam epitaxy, a surface analysis system is attached to the other chamber. Another example of such an auxiliary chamber is a high-pressure reaction chamber for catalysis studies. Sample transport with these systems is accomplished using transfer arms. Some of these complete systems can be very costly.

4.5 Energy Dispersive X-ray Analysis

Energy dispersive X-ray analysis (EDX) is a widely used technique with which to analyze materials with a SEM. EDX instrumentation can be added to most SAMs. This method detects X-rays produced as the result of electron beam bombardment of a solid, namely the other de-excitation process besides Auger electron production. The X-rays are produced to a depth of about 1–3 µm and are observed with a lithium-doped silicon detector that is cooled with liquid nitrogen. Depending on the design of the detector assembly, the elements starting with boron or sodium throughout the periodic chart are observable. The minimum volume that can be analyzed is about 1 µm³, even though the electron beam diameter may be much smaller. This is because scattering of the primary beam and subsequent redistributed electrons can create detectable X-rays beyond the initial electron beam impact area. In order to obtain the best use of this technique, the placement of an EDX in a SAM requires careful consideration with relation to the sample position and the incident electron beam. 

4.6 Residual Gas Analyzer

A residual gas analyzer is a very useful addition to a surface analysis system that is relatively inexpensive. Most of these analyzers are small quadrupole mass spectrometers. They can be employed to test for an occasional leak in the vacuum system. The usual indication of a leak is a peak at 32 Da that indicates oxygen. In order to locate the source of the leak a very small stream of helium (from a glass or plastic capillary) is directed to potential problem sites. One of the most common problems is that a flange has not been sealed properly; less likely sources are the various feedthroughs, windows, and mechanical transfer assemblies. Very rarely does a weld fail to give a measurable leak.

The mass spectrometer also is useful to check the purity of sputter gases and to check the background composition in the analysis chamber. The identity of the gas phase species can be deduced if there is a relatively large amount of outgassing from a specimen. This can provide additional information about a specimen.

The mass spectrometer should have a range of 1−100 Da. Some small mass spectrometers can analyze up to a few hundred daltons. The two main types of detectors employed are a Faraday cup and an electron multiplier. The Faraday cup detector has a detection limit in the low 10⁻¹⁰ torr region for most gases. The electron multiplier can detect species with a relative partial pressure about three to four orders of magnitude lower than the Faraday cup. Many of the small quadrupole mass spectrometers have both detector types. The mass spectrometers can be computer controlled or have a separate electronic package and recording system.

5 CONCLUSIONS

XPS and AES are widely used techniques for the analysis of the surface region of solids. The elemental and often the chemical environment of surfaces can be identified using either technique. The spatial distribution of the detected species can be determined to less than 5 µm with XPS and under 20 nm with AES on a routine basis. Both can be employed in a wide range of basic and applied investigations. Variations in the depth distribution of elements can be obtained by sputter profiles. However, as with any sophisticated analysis method, care has to be used in evaluating any but the relatively routine analytical problems. The capabilities of these techniques have been expanded greatly since they were first introduced, and their development continues.

The use of X-ray methods in the field of materials analysis is now entering its seventh decade. While the broad definition of X-ray methods covers many techniques based on the scatter, emission and absorption properties of X-radiation, the two most common are X-ray fluorescence (XRF) spectrometry and X-ray powder diffractometry (XRD). When a sample of material is bombarded with energetic radiation (X-rays, γ-rays, electrons, protons, etc.) vacancies may arise from the removal of inner orbital electrons. One of the processes by which the atom regains stability is by transference of electrons from outer to inner electron shells. Each of these transitions is accompanied by the emission of an X-ray photon having an energy equal to the energy difference between the two states. The X-ray emission wavelengths are characteristic of the atom in question and there is a simple relationship (Moseley’s law) between the wavelength of the emission line and the atomic number of the atom. Thus when a sample is made up of many different types of atoms, each atom will produce a series of wavelengths, and all of the contributions add up to become the total X-ray emission from the sample. XRF is a technique which utilizes the diffracting power of a single crystal, or the proportional characteristics of a photon detector, to separate the polychromatic beam of radiation from the sample into separate wavelengths, thus allowing qualitative and quantitative elemental measurements to be made.

A beam of monochromatic radiation may also be scattered when X-ray photons collide with atomic electrons. Where the scattered wavelengths interfere with one another diffraction of X-rays occurs. All substances are built up of individual atoms and nearly all substances have some degree of order of periodicity in the arrangement of these atoms. It is the scattering from these periodic arrays that leads to the diffraction effect, and there is a simple relationship (Bragg’s law) between the scattering
angle, the wavelength of the radiation and the spacings between the planes of atoms. Since the distances between the atomic planes are dependent on the size and distribution of atoms – i.e. the structure of the material, XRD can be used for qualitative and quantitative phase identification.

1 INTRODUCTION

1.1 Brief History of the Development of X-ray Methods

X-ray photons are a form of electromagnetic radiation produced following the ejection of an inner orbital electron and subsequent transition of atomic orbital electrons from states of high to low energy. When a monochromatic beam of X-ray photons falls onto a given specimen three basic phenomena may result, namely absorption, scatter or fluorescence. The coherently scattered photons may undergo subsequent interference leading in turn to the generation of diffraction maxima. These three basic phenomena form the bases of three important X-ray methods: the absorption technique, which is the basis of radiographic analysis; the scattering effect, which is the basis of X-ray diffraction; and the fluorescence effect, which is the basis of XRF spectrometry.

X-rays were discovered by Wilhelm Roentgen in 1895 and the property of the atomic number dependence of the absorption of X-ray photons was quickly established and applied for medical diagnostic purposes. Following the discovery of the diffraction of X-rays by Max von Laue in 1913, two major fields of materials analysis have developed. XRF spectrometry uses either the diffracting power of a single crystal to isolate narrow wavelength bands, or a proportional detector to isolate narrow energy bands, from the polychromatic radiation (including characteristic radiation) excited in the sample.

The second field of materials analysis involves characterization by means of atomic arrangement in the crystal lattice. XRD uses single or multiphase specimens comprising a random orientation of small crystallites, each of the order of 1–50 µm in diameter. Each crystallite in turn is made up of a regular, ordered array of atoms. An ordered arrangement of atoms (the crystal lattice) contains planes of high atomic density which in turn means planes of high electron density. A monochromatic beam of X-ray photons will be scattered by these atomic electrons and if the scattered photons interfere with each other, diffraction maxima may occur. In general, one diffracted line will occur for each unique set of planes in the lattice. A diffraction pattern is typically in the form of a graph of diffraction angle (or interplanar spacing) against diffracted line intensity. The pattern is thus made up of a series of superimposed diffractograms, one for each unique phase in the specimen. Each of these unique patterns can act as an empirical “fingerprint” for the identification of the various phases, using pattern recognition techniques based on a file of standard single-phase patterns. Quantitative phase analysis is also possible, albeit with some difficulty because of various experimental and other problems, not the least of which is of the large number of diffraction lines occurring from multiphase materials.

1.2 Role of X-ray Methods in the Modern Analytical Laboratory

Wavelength-dispersive spectrometers have been commercially available since the early 1950s and there are probably about 20,000 units in use in the world today. Energy-dispersive spectrometer systems became available in the early 1970s, and there are probably about 8000 stand-alone spectrometers in use, with perhaps slightly more than this number attached to scanning electron microscopes. XRF analysis finds a wide range of application since it allows the quantitation of all elements in the periodic table from F (atomic number 9) upwards. Newer developments allow the determination of the ultralow atomic number elements including B, C, O and N. Accuracies of a few tenths of one percent are possible for most of the atomic number range, and elements are detectable in many cases to the low parts per million level. Excellent data treatment software is available allowing the rapid application of quantitative and semi-quantitative procedures.
X-ray powder diffractometers have been available in their modern form since the late 1940s, although camera systems were available back to the 1920s. There are probably of the order of 30,000 powder diffractometers in use – about half of these being automated to some degree. XRD is applicable to any ordered (crystalline) material and although much less accurate or sensitive than the fluorescence method, is almost unique in its ability to differentiate phases. Quantitative phase analysis is possible, but the accuracy of a determination is often compromised by preferred orientation of the specimen.

The fluorescence and diffraction techniques are to a large extent complementary, since one allows accurate quantitation of elements to be made and the other allows qualitative and semiquantitative estimations to be made of the way in which the matrix elements are combined to make up the phases in the specimen. Thus a combination of the two techniques will often allow the accurate determination of the material balance of a sample.

2 PROPERTIES OF X-RADIATION

2.1 Continuous and Characteristic Radiation

When a high-energy electron beam is incident upon a specimen, one of the products of the interaction is an emission of a broad-wavelength band of radiation called continuum, also referred to as white radiation or bremsstrahlung. This white radiation is produced as the impinging high-energy electrons are decelerated by the atomic electrons of the elements making up the specimen. The intensity/wavelength distribution of this radiation is typified by a minimum wavelength, \( \lambda_{\text{min}} \), which is inversely proportional to the maximum accelerating potential, \( V \), of the electrons. The intensity distribution of the continuum reaches a maximum at a wavelength \( 1.5 \) to \( 2 \) times greater than \( \lambda_{\text{min}} \). Increasing the accelerating potential causes the intensity distribution of the continuum to shift towards shorter wavelengths. Most commercially available spectrometers utilize a sealed X-ray tube as an excitation source, and these tubes typically employ a heated tungsten filament as a source of electrons, and a layer of pure metal, such as chromium, rhodium or tungsten, as the anode. The broad band of white radiation produced by this type of tube is ideal for the excitation of the characteristic lines from a wide range of atomic numbers. In general, the higher the atomic number of the anode material, the more intense the beam of radiation produced by the tube. X-ray diffractometers typically employ a more focused filament assembly (12 \( \times \) 0.05 mm) and run at a somewhat lower loading than the XRF tube. A key factor in the design of an X-ray tube for powder diffraction is the specific loading (watts per mm²) of the tube.

2.2 X-ray Spectra

In addition to electron interactions leading to the production of white radiation, there are also electron interactions which produce characteristic radiation. If a high-energy particle, such as an electron, strikes a bound atomic electron, and the energy of the particle is greater than the binding energy of the atomic electron, it is possible that the atomic electron will be ejected from its atomic position, departing from the atom with a kinetic energy \( (E - \phi) \) equivalent to the difference between the energy \( E \) of the initial particle and the binding energy \( \phi \) of the atomic electron. Where the exciting particles are X-ray photons, the ejected electron is called a photoelectron and the interaction between primary X-ray photons and atomic electrons is called the photoelectric effect. As long as the vacancy in the shell exists, the atom is in an unstable state and can regain stability by transference of an electron from one of the outer orbitals to fill the vacancy. The energy difference between the initial and final states of the transferred electron may be given off in the form of an X-ray photon. Since all emitted X-ray photons have energies proportional to the differences in the energy states of atomic electrons, the lines from a given element will be characteristic of that element. The relationship (Equation 1) between the wavelength of a characteristic X-ray photon and the atomic number \( Z \) of the excited element was first established by Moseley.\(^{5}\)

\[
\frac{1}{\lambda} = K(Z - \sigma)^2
\]  

(1)

in which \( K \) is a constant that takes on different values for each spectral series, \( \sigma \) is the shielding constant that has a value of just less than unity. The wavelength of the X-ray photon is inversely related to the energy \( E \) of the photon according to Equation (2):

\[
\lambda(\text{Å}) = \frac{12.4}{E(\text{keV})}
\]  

(2)

Not all vacancies result in the production of characteristic X-ray photons since there is a competing internal rearrangement process known as the Auger effect.\(^{6}\) The ratio of the number of vacancies resulting in the production of characteristic X-ray photons to the total number of vacancies created in the excitation process is called the fluorescent yield. Fluorescent yield values are several orders of magnitude less for the very low atomic numbers. In practice this means that if, for example, one were to compare the intensities obtained from pure barium (\( Z = 56 \)) and pure aluminum (\( Z = 13 \)), all other things being equal, pure barium would give about 50 times more counts than would pure aluminum. The L fluorescent yield for a given atomic number is always less by about a factor of three than the corresponding K
fluorescent yield, where K and L refer to the first and second electron shells. An excited atom can revert to its original ground state by transferring an electron from an outer atomic level to fill the vacancy in the inner shell. An X-ray photon is emitted from the atom as part of this de-excitation step, the emitted photon having an energy equal to the energy difference between the initial and final states of the transferred electron. The selection rules for the production of normal (diagram) lines require that the principal quantum number \( n \) must change by at least one, the angular quantum number \( \ell \) must change by \( \pm 1 \), and the \( J \) quantum number (the total momentum \( \vec{J} \) of an electron is given by the vector sum of \( \ell + s \) where \( s \) is the spin quantum number) must change by 0 or 1. In effect this means that for the K series only \( p \rightarrow s \) transitions are allowed, yielding two lines for each principal level change. Vacancies in the L level follow similar rules and give rise to L series lines. There are more of the L lines since \( p \rightarrow s \), \( s \rightarrow p \) and \( d \rightarrow p \) transitions are all allowed within the selection rules. Transition groups may now be constructed, based on the appropriate number of transition levels.

Figure 1 shows plots of the reciprocal of the square root of the wavelength, as a function of atomic number, for the K, L and M series. As indicated by Moseley’s law such plots should be linear. A scale directly in wavelength may be added, to indicate the range of wavelengths over which a given series occurs. In practice, the number of lines observed from a given element will depend upon the atomic number of the element, the excitation conditions and the wavelength range of the spectrometer employed.

Generally, commercial spectrometers cover the K series, the L series and the M series, corresponding to transitions to K, L and M levels respectively. There are many more lines in the higher series and for a detailed list of all of the reported wavelengths the reader is referred to the work of Bearden. In X-ray spectrometry most of the analytical work is carried out using either the K or the L series wavelengths.

While most of the observed fluorescent lines are normal, certain lines may also occur in X-ray spectra that do not at first sight fit the basic selection rules. These lines are called forbidden lines and are shown in the center portion of Figure 1. Forbidden lines typically arise from outer orbital levels where there is no sharp energy distinction between orbitals. A third type of line may also occur – called satellite lines – which arise from dual ionizations. Neither forbidden transitions nor satellite lines have great analytical significance; they may cause some confusion in qualitative interpretation of spectra and may even be misinterpreted as coming from trace elements. Most commercially available X-ray spectrometers have a range from about 0.2 to 20 Å (60–0.6 keV, 1 Å \( = 10^{-10} \) m \( = 10^{-8} \) nm) which will allow measurement of the K series from F (\( Z = 9 \)) to Lu (\( Z = 71 \)), and for the L series from Mn (\( Z = 25 \)) to U (\( Z = 92 \)). Other line series can occur from the M and N levels but these have little use in analytical X-ray spectrometry.

2.3 Absorption

When a beam of X-ray photons falls onto an absorber, a number of different processes may occur. The more important of these are illustrated in Figure 2. In this example, a monochromatic beam of radiation of wavelength \( \lambda_0 \) and intensity \( I_0 \), is incident on an absorber of thickness \( x_a \) and density \( \rho_a \). The fate of each individual X-ray photon is governed by the following processes. Absorption occurs where only a certain fraction \( (I/I_0) \) of the radiation may pass through the absorber. Where

![Figure 1](image1.png)  
**Figure 1** Moseley diagrams for the K, L and M series. (Reproduced from Jenkms, X-ray Fluorescence Spectrometry, 2nd edition, Wiley-Interscience, 1999. With permission from John Wiley & Sons.)

![Figure 2](image2.png)  
**Figure 2** Interaction of X-ray photons with matter.
this happens the wavelength of the transmitted beam is unchanged and the intensity of the transmitted beam $I(\lambda_0)$ is given by Equation (3):

$$I(\lambda_0) = I_0 \exp(-\mu_a \rho_a x_a)$$

where $\mu_a$ is the mass attenuation coefficient of absorber $a$ for the wavelength $\lambda_0$.

It will be apparent from the above that a number of photons equal to $(I_0 - I)$ have been lost in the absorption process, most of this loss being due to the photoelectric effect. Photoelectric absorption, usually designated $\tau$, will occur at each of the energy levels of the atom. Thus the total photoelectric absorption will be determined by the sum of each individual absorption within a specific shell. The value of the mass attenuation $\mu$ referred to in Equation (3) is a function of both the photoelectric absorption and the scatter, Equation (4):

$$\mu = f(\tau) + f(\sigma)$$

However, $f(\tau)$ is usually large in comparison with $f(\sigma)$. Because the photoelectric absorption is made up of absorption in the various atomic levels, it is an atomic-number-dependent function. A plot of $\mu$ against $\lambda$ contains a number of discontinuities called absorption edges, at wavelengths corresponding to the binding energies of the electrons in the various subshells. The absorption discontinuities are a major source of non-linearity between X-ray intensity and composition in both XRF and XRD.

### 2.4 Scattering

Scatter, $\sigma$, will occur when an X-ray photon collides with one of the electrons of the absorbing element. Where this collision is elastic, i.e. when no energy is lost in the collision process, the scatter is said to be coherent (Rayleigh) scatter. Since no energy change is involved, the coherently scattered radiation will retain exactly the same wavelength as the incident beam. As will be shown later, X-ray diffraction is a special case of coherent scatter, where the scattered photons interfere with each other. It can also happen that the scattered photon gives up a small part of its energy during the collision, especially where the electron with which the photon collides is only loosely bound. In this instance the scatter is said to be incoherent (Compton scatter) and the wavelength of the incoherently scattered photon will be greater than $\lambda_0$.

### 2.5 Role of Crystal Structure in X-ray Scattering and Diffraction

All substances are built up of individual atoms and nearly all substances have some degree of order of periodicity in the arrangement of these atoms. A crystal can be defined as a homogeneous, anisotropic body having the natural shape of a polyhedron. In practical terms, whether a substance is homogeneous or not can only be defined by the means that are available for measuring the crystallinity. In general, the shorter the wavelength, the smaller the crystalline region that is able to be recognized. Even noncrystalline materials have a degree of order and each will give some sort of a diffraction pattern. For example, glassy materials and liquids will give diffraction patterns of sorts, generally in the form of one or more broad diffuse peaks or halos. In XRD one is generally dealing exclusively with crystalline materials. The diffraction pattern can, moreover, be used to determine the degree of crystallinity, that is the dimensions of the crystalline regions in otherwise amorphous substances. A crystalline substance has a definite form which is retained no matter what the physical size of the crystal. A certain type of crystal can thus be defined in terms of specific physical characteristics which determine its shape. For example, a sodium chloride crystal has cubic symmetry and by definition the angles between all of the principal faces should be 90°. In fact there are other crystal classes which also have angles between faces of 90°, but the cube is unique in that the lengths of the sides are also equal. If our sodium chloride crystal were reduced in size until the smallest repeat unit was found (the so-called unit cell) it would indeed be found that all sides were equal. Hence it is apparent that a crystal type can be defined in terms of the lengths of the sides of its unit cell and the angles between the faces. Since every ordered material is made up of a unique arrangement and number of atoms, every ordered material will give a diffraction pattern which is, to all intents and purposes, also unique.

Figure 3 illustrates in a simplified manner the diffraction patterns that would be obtained from (a) a single...
crystal, (b) an oriented powder and (c) a random powder. In each instance the specimen is placed between a monochromatic beam of radiation and a piece of photographic film. In the case of the single crystal, because only certain crystal planes are in the position to diffract radiation onto the film, the pattern will appear as a series of spots on the film, the position of the spots being dependent upon the structure and orientation of the crystal. Changing the position of the crystal will bring other planes into diffracting position and the pattern of spots will change. In the case of a random powder, whatever the orientation of the specimen there is always a sufficient number of crystallites to diffract from the appropriate \( d \)-spacings(s) (see section 2.6). In the case of an oriented powder, however, there are more crystallites in certain orientations and less in others. Thus the pattern obtained is somewhere between the single-crystal and the random-powder patterns.

### 2.6 Interference and Diffraction Effects

As illustrated in Figure 4(a), a crystal lattice consists of a regular arrangement of atoms, with layers of high atomic density existing throughout the crystal structure. Planes of high atomic density means planes of high electron density. Since scattering occurs between impinging X-ray photons and the loosely bound outer orbital atomic electrons, when a monochromatic beam of radiation falls onto the high atomic density layers scattering will occur. In order to satisfy the requirement for constructive interference, it is necessary that the scattered waves originating from the individual atoms, the scattering points, be in phase with one another. The geometric conditions for this condition to occur are illustrated in Figure 4(b). Here, a series of parallel rays strike a set of crystal planes at an angle \( \theta \) and are scattered as previously described. Reinforcement will occur when the difference in the path lengths of the two interfering waves is equal to a whole number of wavelengths. This path length difference is \( 2d \sin \theta \) where \( d \) is the inter-planar spacing; hence the overall condition (Equation 5) for reinforcement is that:

\[
n \lambda = 2d \sin \theta
\]

where \( n \) is an integer. Equation (5) is a statement of Bragg’s law. Diffraction experiments are generally made at a fixed wavelength, thus a measure of the diffraction angles will allow the associated \( d \)-spacings to be calculated. Bragg’s law is also important in wavelength-dispersive spectrometry since by using a crystal of fixed \( 2d \), each unique wavelength will be diffracted at a unique diffraction angle. Thus, measuring the diffraction angle \( 2\theta \) allows the determination of the wavelength (inter-planar spacing) if the \( d \)-spacing of the crystal is known. Since there is a simple relationship between wavelength and atomic number, one can establish the atomic number(s) of the element(s) from which the wavelengths were emitted.

### 3 INSTRUMENTATION FOR X-RAY FLUORESCENCE ANALYSIS

X-ray spectrometers fall roughly into two categories: wavelength-dispersive instruments and energy-dispersive instruments. The wavelength-dispersive system was introduced commercially in the early 1950s and since the mid-1970s has developed into a widely accepted analytical tool. Analytical chemists have available to them a wide range of instruments for the qualitative and quantitative analysis of multielement samples, and in the choice of technique they will generally consider such factors as sensitivity, speed, accuracy, cost, range of applicability, and so on. Within the two major categories of X-ray spectrometers specified, there is of course a wide diversity of instruments available but most of these will fit the four basic types:

- simultaneous wavelength-dispersive
- sequential wavelength-dispersive
- bremsstrahlung source energy-dispersive
- secondary target energy-dispersive.

Although these different types of instrument may bear little physical resemblance to one another, for the purpose of comparison they differ only in the type of source used.
for excitation, the number of elements which they are able to measure at one time, the speed at which they collect data and finally, their price range. All of the instruments listed above are, in principle at least, capable of measuring all elements in the periodic classification from \( Z = 9 \) (F) and upwards. All can be fitted with multisample handling facilities and all can be automated by use of minicomputers. All are capable of precision of the order of a few tenths of one percent and all have sensitivities down to the low parts per million level. As far as the analyst is concerned, they differ only in their speed, cost and number of elements measurable at the same time.

Single-channel wavelength-dispersive spectrometers are typically employed for both routine and nonroutine analysis of a wide range of products, including ferrous and nonferrous alloys, oils, slags and sinters, ores and minerals, thin films, and so on. These systems are very flexible but relative to multichannel spectrometers are somewhat slow. The multichannel wavelength-dispersive instruments are used solely for routine, high throughput, analyses where the great need is for fast accurate analysis, but where flexibility is of no importance. Energy-dispersive spectrometers have the great advantage of being able to display information on all elements at the same time. They lack somewhat in resolution over the wavelength-dispersive systems but also find great application in quality control, troubleshooting problems, and so on. They have been particularly effective in the fields of scrap alloy sorting, in forensic science and in the provision of elemental data to supplement X-ray powder diffraction data.

3.1 Basis of the Method

All conventional X-ray spectrometers comprise three basic parts: the primary source unit, the spectrometer itself and the measuring electronics. The primary source unit consists of a very stable high-voltage generator, capable of providing up to around 3 kW of power at a potential of typically 60–80 kV, plus a sealed X-ray tube. The sealed X-ray tube has an anode of Cr, Rh, W, Ag, Au or Mo and delivers an intense source of continuous radiation which then impinges on the analyzed specimen where characteristic radiation is generated. A portion of the characteristic ‘fluorescence’ radiation is then collected by the actual spectrometer where the beam is passed via a collimator or slit onto the surface of an analyzing crystal, where individual wavelengths are diffracted in accordance with the Bragg law. A photon detector, typically a gas flow or a scintillation counter, is then used to convert the diffracted characteristic photons into voltage pulses which are integrated and displayed as a measure of the characteristic line intensity.

3.2 X-ray Sources

Several different types of source have been employed for the excitation of characteristic X-radiation, including those based on electrons, X-rays, \( \gamma \)-rays, protons and synchrotron radiation. Sometimes a bremsstrahlung X-ray source is used to generate specific X-radiation from an intermediate pure element sample called a secondary fluorescer. By far the most common source today is the X-ray photon source. This source is used in primary mode in the wavelength- and primary energy-dispersive systems, and in secondary fluorescer mode in secondary target energy-dispersive spectrometers. A \( \gamma \)-source is typically a radioisotope that is used either directly, or in a mode equivalent to the secondary fluorescer mode in energy-dispersive spectrometry. Most conventional wavelength-dispersive X-ray spectrometers use a high power (2–4 kW) X-ray bremsstrahlung source. Energy-dispersive spectrometers use either a high-power or low-power (0.5–1.0 kW) primary source, depending on whether the spectrometer is used in the secondary or primary mode. In all cases, the primary source unit consists of a very stable high-voltage generator, capable of providing a potential of typically 40–100 kV. The current from the generator is fed to the filament of the X-ray tube, which is typically a coil of tungsten wire. The applied current causes the filament to glow, emitting electrons. A portion of this electron cloud is accelerated to the anode of the X-ray tube, which is typically a water-cooled block of copper with the required anode material plated or cemented to its surface. The impinging electrons produce X-radiation, a significant portion of which passes through a thin beryllium window to the specimen.

3.3 X-ray Detectors

An X-ray detector is a transducer for converting X-ray photon energy into voltage pulses. Detectors work through a process of photoionization in which interaction between the entering X-ray photon and the active detector material produces a number of electrons. The current produced by these electrons is converted to a voltage pulse, by a capacitor and resistor, such that one digital voltage pulse is produced for each entering X-ray photon. In addition to being sensitive to the appropriate photon energies, which means being applicable to a given range of wavelengths or energies, there are two other important properties that an ideal detector should possess. These properties are proportionality and linearity. Each X-ray photon entering the detector produces a voltage pulse, and where the size of the voltage pulse is proportional to the photon energy, the detector is said to be proportional. Proportionality is needed where the technique of pulse height selection is to be used. Pulse height selection is a means of electronically rejecting
pulses of voltage levels other than those corresponding to the characteristic line being measured. X-ray photons enter the detector at a certain rate and where the output pulses are produced at this same rate the detector is said to be linear. Linearity is important where the various count rates produced by the detector are to be used as measures of the photon intensity for each measured line.

In the case of wavelength-dispersive spectrometers, the gas flow proportional counter is generally employed for the measurement of longer wavelengths and the scintillation counter is used for the measurement of shorter wavelengths. Neither of these detectors has sufficient resolution to separate multiple wavelengths on its own, and so they have to be employed along with an analyzing crystal. However, in the case of energy-dispersive spectrometry, where no dispersing crystal is employed, a detector of higher resolution must be used.

3.4 The Wavelength-dispersive Spectrometer
In order to maintain the required geometric conditions a goniometer is used to ensure that the angle between source and crystal, and crystal and detector, is kept the same. The output from a wavelength-dispersive spectrometer may be either analog or digital. For qualitative work an analog output is traditionally used, and in this instance a rate meter is used to integrate the pulses over short time intervals, typically of the order of a second or so. The output from the rate meter is fed to an x/t recorder which scans at a speed which is conveniently coupled with the goniometer scan speed. The recorder thus displays an intensity/time diagram, which becomes an intensity/2π diagram. Tables are then used to interpret the wavelengths. For quantitative work it is more convenient to employ digital counting, and a timer/scaler combination is provided which will allow pulses to be integrated over a period of several tens of seconds and then displayed as count or count rate.

Most modern wavelength-dispersive spectrometers are controlled in some way by a minicomputer or microprocessor and by use of specimen changers are capable of very high specimen throughput. Once they are set up the spectrometers will run virtually unattended for several hours.

3.5 The Energy-dispersive Spectrometer
Like the wavelength-dispersive spectrometer, the energy-dispersive spectrometer also consists of the three basic units – excitation source, spectrometer and detection system. In this case, however, the detector itself acts as the dispersion agent. The detector generally employed in this context is the Si(Li) detector. The Si(Li) detector consists of a small cylinder (about 1 cm diameter and 3 mm thick) of p-type silicon that has been compensated by lithium to increase its electrical resistivity. A Schottky barrier contact on the front of the silicon disk produces a p-i-n type diode (one with p-doped, isolating and n-doped layers). In order to inhibit the mobility of the lithium ions and to reduce electronic noise, the diode and its pre-amplifier are cooled to the temperature of liquid nitrogen. Incident X-ray photons interact to produce a specific number of electron hole pairs. The charge produced is swept from the diode by the bias voltage to a charge-sensitive pre-amplifier. A charge loop integrates the charge on a capacitor to produce an output pulse. A pre-amplifier is responsible for collecting this charge on a feedback capacitor to produce a voltage pulse proportional to the original X-ray photon energy. Thus when a range of photon energies are incident upon the detector, an equivalent range of voltage pulses is produced as a detector output. A multichannel analyzer is used to sort the arriving pulses at its input in the same fashion as to produce a histogram representation of the X-ray energy spectrum.

The output from an energy-dispersive spectrometer is generally displayed on some sort of visual display unit. The operator is able to dynamically display the contents of the various channels as an energy spectrum and provision is generally made to allow zooming in on portions of the spectrum of special interest, to overlay spectra, to subtract background, and so on, in a rather interactive manner. As in the case of the modern wavelength-dispersive systems, nearly all energy-dispersive spectrometers will incorporate some form of minicomputer which is available for spectral stripping, peak identification, quantitative analysis and a host of other useful functions.

4 ELEMENTAL ANALYSIS BY X-RAY FLUORESCENCE

4.1 Specimen Preparation Techniques for X-ray Fluorescence
Because X-ray spectrometry is essentially a comparative method of analysis, it is vital that all standards and unknowns be presented to the spectrometer in a reproducible and identical manner. Any method of specimen preparation must give specimens that are reproducible and which, for a certain calibration range, have similar physical properties including mass attenuation coefficient, density, particle size and particle homogeneity. In addition the specimen preparation method must be rapid and cheap and must not introduce extra significant systematic errors, for example the introduction of trace elements from contaminants in a diluent. Specimen preparation is an all important factor in the ultimate accuracy of any X-ray determination, and many papers have been published.
describing a multitude of methods and recipes for sample handling. In general samples fit into three main categories:

- Samples which can be handled directly following some simple pretreatment such as pelletizing or surfacing, for example homogeneous samples of powders, bulk metals or liquids.
- Samples which require significant pretreatment, for example heterogeneous samples, samples requiring matrix dilution to overcome inter-element effects and samples exhibiting particle size effects.
- Samples which require special handling treatment, for example samples of limited size, samples requiring concentration or prior separation and radioactivity.

The ideal specimen for XRF analysis is one in which the analyzed volume of specimen is representative of the total specimen, which is, itself, representative of the sample submitted for analysis. There are many forms of specimen suitable for XRF analysis, and the form of the sample as received will generally determine the method of pretreatment. It is convenient to refer to the material received for analysis as the sample, and that which is actually analyzed in the spectrometer as the specimen. While the direct analysis of certain materials is certainly possible, more often than not some pretreatment is required to convert the sample to the specimen. This step is referred to as specimen preparation. In general, the analyst would prefer to analyze the sample directly, because if it is taken as received any problems arising from sample contamination that might occur during pretreatment are avoided. In practice, however, there are three major constraints that may prevent this ideal circumstance from being achieved: sample size, sample size homogeneity and sample composition heterogeneity. Problems of sample size are frequently severe in the case of bulk materials such as metals, large pieces of rock, etc.

Problems of sample composition heterogeneity will generally occur under these circumstances as well, and in the analysis of powdered materials, heterogeneity must almost always be considered. The sample as received may be either homogeneous or heterogeneous; in the latter case, it may be necessary to render the sample homogeneous before an analysis can be made. Heterogeneous bulk solids are generally the most difficult kind of sample to handle, and it may be necessary to dissolve or chemically react the material in some way to give a homogeneous preparation. Heterogeneous powders are either ground to a fine particle size and then pelleted, or fused with a glass-forming material such as borax. Solid material in liquids or gases must be filtered out and the filter analyzed as a solid. Where analyte concentrations in liquids or solutions are too high or too low, dilution or preconcentration techniques may be employed to bring the analyte concentration within an acceptable range.

4.2 Qualitative Analysis with the X-ray Spectrometer

Both the simultaneous wavelength-dispersive spectrometer and the energy-dispersive spectrometers lend themselves admirably to the qualitative analysis of materials. As was shown in Equation (1) there is a simple relationship between the wavelength or energy of a characteristic X-ray photon, and the atomic number of the element from which the characteristic emission line occurs. Thus by measuring the wavelengths, or energies, of a given series of lines from an unknown material the atomic numbers of the excited elements can be established. Because the characteristic X-ray spectra are so simple the actual process of allocating atomic numbers to the emission lines is a relatively simple process and the chance of making a gross error is rather small. In comparison, the procedures for the qualitative analysis of multiphase materials with the X-ray powder diffractometer is a much more complex business. There are after all only 100 or so elements, and within the range of the conventional spectrometer each element gives, on an average, only a dozen lines. In diffraction on the other hand, there are perhaps as many as several million possible compounds, each of which can give on average 50 or so lines. Similarly if one compares the X-ray emission spectrum with the ultraviolet (UV) emission spectrum, the X-ray spectrum is much easier to interpret than the UV emission spectrum because the X-ray spectrum arises from inner orbital transitions, the number of which is of course rather limited, and the UV spectrum arises from transitions to unfilled levels, of which there can be many. A further benefit of the X-ray emission spectrum for qualitative analysis is that because transitions do arise from inner orbitals, the effect of chemical combination, i.e. valence, is almost negligible.

4.3 Development of Intensity/Concentration Algorithms

The great flexibility and range of the various types of XRF spectrometer, coupled with their high sensitivity and good inherent precision make them ideal for quantitative analysis. Like all instrumental methods of analysis the high precision can be translated into high accuracy only if the various systematic errors in the analysis process are taken care of. The precision of a well-designed X-ray spectrometer is typically of the order of one tenth of a percent or so, the major source of this random error being the X-ray source, the high voltage generator plus the X-ray tube. In addition there is an error arising from the statistics of the actual counting process.
Systematic errors in quantitative X-ray spectrometry arise mainly from absorption- and specimen-related phenomena, rather like in X-ray powder diffraction except that in the spectrometry case they are much more complicated. This is because in spectrometry many wavelengths are involved, whereas in diffraction one is dealing with a single wavelength, i.e. the diffracted, monochromatic tube line. This means, for example, that the equivalent absorption-effect expression becomes rather complex. Although these so-called matrix effects are somewhat complicated, many excellent methods have been developed over the past 30 years or so for handling them. The advent of the personal computer controlled spectrometer has done much to enhance the application of these correction procedures and today, in most cases, one is able to quantify most elements in the periodic table of atomic number 9 (F) and upwards to an accuracy of a few tenths of a percent. The areas of application of the XRF technique now cover almost all areas of inorganic analysis.

In the conversion of net line intensity to analyte concentration it may be necessary to correct for any absorption and/or enhancement effects which occur. Absorption effects include both primary and secondary absorption. Primary absorption occurs because all atoms of the specimen matrix will absorb photons from the primary source. Since there is a competition for these primary photons by the atoms making up the specimen, the intensity/wavelength distribution of these photons available for the excitation of a given analyte element may be modified by other matrix elements. Secondary absorption refers to the effect of the absorption of characteristic analyte radiation by the specimen matrix. As characteristic radiation passes out from the specimen in which it was generated, it will be absorbed by all matrix elements, by amounts relative to the mass attenuation coefficients of these elements. The total absorption of a specimen is dependent on both primary and secondary absorption. Enhancement effects occur when a non-analyte matrix element A emits a characteristic line that has an energy just in excess of the absorption edge of the analyte element. This means that the nonanalyte element in question is able to excite the analyte, giving characteristic photons over and above those produced by the primary continuum. This gives an increased, or enhanced, signal from the analyte.

Since the early work of Sherman\(^8\) there has been a growing interest in the provision of an intensity/concentration algorithm which would allow the calculation of the concentration values without recourse to the use of standards. Sherman’s work was improved upon first by the Japanese team of Shiraiwa and Fujino\(^9\) and later, by Criss and Birks\(^{10,11}\) with their Naval Research Laboratory X-ray Fluorescence program (NRLXRF). The same group also solved the problem of describing the intensity distribution from the X-ray tube.\(^{12}\) The problem for the average analyst in the late 1960s and early 1970s, however, remained that of finding sufficient computational power to apply these methods. In the early 1970s, de Jongh suggested an elegant solution\(^{13}\) in which he proposed the use of a large mainframe computer for the calculation of the influence coefficients, then use of a minicomputer for their actual application using a concentration correction influence model.

### 4.4 Quantitative Methods

The simplest quantitative analysis situation to handle is the determination of a single element in a known matrix. In this instance, a simple calibration curve of analyte concentration vs line intensity is sufficient for quantitative determination. A slightly more difficult case might be the determination of a single element where the matrix is unknown. Three basic methods are commonly employed in this situation; use of internal standards, use of standard addition or use of a scattered line from the X-ray source. The most complex case is the analysis of all, or most, of the elements in a sample, about which little or nothing is known. In this case a full qualitative analysis would be required before any attempt is made to quantitate the matrix elements. Once the qualitative composition of the sample is known, again, one of three general techniques is typically applied; use of type standardization, use of an influence coefficient method or use of a fundamental parameter technique. Both the influence coefficient method and the fundamental parameter technique require a computer for their application. In principle, an empirical correction procedure can be described as the correction of an analyte element intensity for the influence of an interfering element(s) using the product of the intensity from the interfering element line and a constant factor as the correction term.\(^{14}\) This constant factor is generally referred to as an influence coefficient, since it is assumed to represent the influence of the interfering element on the analyte. Commonly employed influence coefficient methods may use either the intensity or the concentration of the interfering element as the correction term. These methods are referred to as intensity correction and concentration correction methods, respectively. Intensity correction models give a series of linear equations which do not require much computation, but they are generally not applicable to wide ranges of analyte concentration. Various versions of the intensity correction models found initial application in the analysis of nonferrous metals where correction constants were applied as look-up tables. Later versions\(^{15}\) were supplied on commercially available computer controlled spectrometers and were used for a wider range of application. A concentration
model\(^{(16)}\) requires the solving of a series of simultaneous equations, by regression analysis or matrix inversion techniques. This approach is more rigorous than the intensity models, and so they became popular in the early 1970s as suitable low-cost minicomputers became available.

Influence coefficient correction procedures can be divided into three basic types: fundamental, derived and regression. Fundamental models are those which require starting with concentrations, then calculating the intensities. Derived models are those which are based on some simplification of a fundamental method but which still allow concentrations to be calculated from intensities. Regression models are those which are semi-empirical in nature, and which allow the determination of influence coefficients by regression analysis of data sets obtained from standards. All regression models have essentially the same form and consist of a weight fraction term, \(W\) (or concentration, \(C\)); an intensity (or intensity ratio) term, \(I\); an instrument-dependent term which essentially defines the sensitivity of the spectrometer for the analyte in question, and a correction term which corrects the instrument sensitivity for the effect of the matrix. The general form is given by Equation (6):

\[
W = I_{\text{instrument}}[1 + \text{[model]}] \tag{6}
\]

Equation (6) shows that the weight fraction \(W\) of an analyte is proportional to the product of measured intensity \(I\) from the analyte, corrected for instrumental effects; and a matrix correction term. Different models vary only in the form of this correction term.

The major advantage to be gained by use of influence coefficient methods is that a wide range of concentration ranges can be covered using a relatively inexpensive computer for the calculations. A major disadvantage is that a large number of well-analyzed standards may be required for the initial determination of the coefficients. However, where adequate precautions have been taken to ensure correct separation of instrument-and matrix-dependent terms, the correction constants are transportable from one spectrometer to another and, in principle, need only be determined once.

4.5 Trace Analysis

The XRF method is particularly applicable to the qualitative and quantitative analysis of low concentrations of elements in a wide range of samples, as well as allowing the analysis of elements at higher concentrations in limited quantities of materials. A measurement of a line at peak position gives a counting rate which, in those cases where the background is insignificant, can be used as a measure of the analyte concentration. However, where the background is significant the measured value of the analyte line at the peak position now includes a count rate contribution from the background. The analyte concentration in this case is related to the net counting rate. Since both peak and background count rates are subject to statistical counting errors, the question now arises as to the point at which the net peak signal is statistically significant. The generally accepted definition for the lower limit of detection (LLD) is that concentration equivalent to two standard deviations of the background counting rate. A formula (Equation 7) for the LLD can now be derived:\(^{(17)}\)

\[
\text{LLD} = \frac{3/m}{R_b/t_b} \tag{7}
\]

In Equation (7) \(R_b\) is the count rate at the background, \(t_b\) is the time spent counting the background and \(m\) is the sensitivity of the spectrometer in c/s/\%. Even though we are using two standard deviations, two measurements, peak and background, must be made. This increases the error by \(\sqrt{2}\). It is the practice to assume that \(2\sqrt{2} \approx 3\), hence the ‘3’ in Equation (7). It is important to note that not only does the sensitivity of the spectrometer vary significantly over the wavelength range of the spectrometer, but so too does the background counting rate. In general, the background varies by about two orders of magnitude over the range of the spectrometer. It will be seen that the detection limit will be best when the sensitivity is high and the background is low. Both the spectrometer sensitivity and the measured background vary with the average atomic number of the sample. While detection limits over most of the atomic number range lie in the low parts per million range, the sensitivity of the X-ray spectrometer falls off quite dramatically towards the long wavelength limit of the spectrometer owing mainly to low fluorescence yields and the increased influence of absorption. As a result, poorer detection limits are found at the long wavelength extreme of the spectrometer, which corresponds to the lower atomic numbers. Thus the detection limits for elements such as fluorine and sodium are at the levels of hundredths of one percent rather than parts per million. The detection limits for the very low atomic number elements such as carbon (\(Z = 6\)) and oxygen (\(Z = 7\)) are very poor, typically of the order of 3 to 5%.

5 INSTRUMENTATION FOR POWDER DIFFRACTION

5.1 Basis of the Method

The powder method derives its name from the fact that the specimen is typically in the form of a microcrystalline powder, although as has been indicated, any material
which is made up of an ordered array of atoms will give a diffraction pattern. The possibility of using a diffraction pattern as a means of phase identification was recognized over 50 years ago but it was not until the late 1930s that a systematic means of unscrambling the superimposed diffraction patterns was proposed.\(^{(18)}\)

The technique was based on the use of a file of single phase patterns, characterized in the first stage by their three strongest reflections and a search technique based on matching strong lines in the unknown pattern with these standard pattern lines. A potential match was then confirmed by a check using the full pattern in question. The identified pattern was then subtracted from the experimental pattern and the procedure repeated on the residue pattern until all lines were identified. Techniques for this “search/matching” process have changed little over the years and, although in the hands of experts manual search/matching is an extremely powerful tool, for the less experienced user it can be rather time-consuming. Round robin tests have indicated that 2–4 hours are typically required for the complete identification of a four-phase mixture.\(^{(19)}\)

A growing complication is that the file of standard patterns increases by about 1500 each year and currently stands at about 118,000 entries. The responsibility for the maintenance of the Powder Data File (PDF) lies with the International Centre for Diffraction Data (ICDD) which is a not-for-profit organization located in Newtown Square, Pennsylvania. This group is made up of a staff of permanent officers along with a number of academic and industrial scientists who are active in the field of XRD. The PDF is a unique assembly of good-quality single-phase patterns and is used by thousands of chemists, geologists, materials scientists, etc. all over the world.

### 5.2 Production of Monochromatic Radiation

With the growing need for high-quality X-ray powder diffraction data, one especially important parameter is the method by which the analytical wavelength is treated. Problems can occur in data treatment because of the polychromatic nature of the diffracted beam and the variability in the angular dispersion of the diffractometer. A combination of these two facts can lead to difficulty in manually assessing where the maximum of a peak occurs, especially in the range of angles from 30° to 60° 2\(\theta\). Of the many methods commonly employed to render the radiation monochromatic (or bichromatic), most will fit into two broad categories – instrumental methods and computer methods. The more common instrumental methods of monochromatization include the following:

- use of a \(\beta\)-filter
- use of a proportional detector and pulse height selection
- use of a Si(Li) solid-state detector
- use of a diffracted-beam monochromator
- use of a primary beam monochromator.

The basic purpose of the monochromatization of the diffracted radiation is to obtain an experimental pattern from a single, unique wavelength. Inspection of Bragg’s law (Equation 5) reveals that each unique \(d\)-spacing will diffract different wavelengths at their own unique diffraction angles. Thus, if a pattern were measured using an X-ray beam containing two wavelengths, the observed pattern would, in fact, be two patterns (one for each wavelength) superimposed on one another, and clearly will be more difficult to interpret than a diffractogram from a single wavelength. While the problems associated with the interpretation of a diffractogram from two known wavelengths can be significant, much more of a problem occurs when additional wavelengths are diffracted. The characteristic K-radiation emission from typical X-ray tube anode materials is much more complex than the simple \(\alpha\)-doublet and \(\beta\)-doublet model generally employed in classical powder diffractometry. For most practical purposes, however, the copper K spectrum is generally considered to consist simply of two pairs of lines, the \(\alpha_1/\alpha_2\)-doublet, occurring from a \(2p \rightarrow 1s\) transition; and the \(\beta_1/\beta_2\)-doublet from a \(3p \rightarrow 1s\) transition. The following table lists the values of the K\(\alpha\) and K\(\beta\) wavelengths for the more common X-ray tube target elements.

<table>
<thead>
<tr>
<th>Anode</th>
<th>(K\alpha_1(100))</th>
<th>(K\alpha_2(50))</th>
<th>(K\beta(15))</th>
</tr>
</thead>
<tbody>
<tr>

</tbody>
</table>

In most experimental work, the \(\beta\)-doublet intensity is typically reduced to less than a few percent of the \(\alpha\)-doublet intensity by use of filtration, or it is removed by use of a diffracted beam monochromator or a high-resolution energy-resolving detector. In each case, what remains is essentially bichromatic X-radiation. The exception to this occurs with the primary beam monochromator where only the \(\alpha_1\) is directed onto the specimen. In applying the usual bichromatic radiation to the measurement of interplanar spacings, the main problems are the angle-dependent dispersion of the \(\alpha_1/\alpha_2\)-doublet, and differences in peak asymmetry between the two. It follows from Bragg’s law that an error in \(d\)-spacing is linearly related to an error in wavelength. For manual qualitative phase identification, an accuracy of about 5 parts in 1000 for \(\Delta d/d\) is sufficient.
and about twice this accuracy is required for computer search/matching. Provided that the true $\alpha_1$-emission line is being used, i.e. either the diffracted beam is really monochromatic, or the contribution from the $\alpha_2$ is effectively removed from the diffraction profile, then the wavelength need also be known only to about 2 parts per 1000. For accurate lattice parameter determination, it is common practice to use an internal standard and, in these cases, the wavelength value is, to all intents and purposes, redundant.

### 5.3 Use of Diffractometers in the Powder Method

A powder diffractometer is essentially a device which allows a range of $\theta$ values to be scanned, rotating the photon detector at twice the angular speed of the specimen thus maintaining the required geometrical condition. The specimen consists of a random distribution of crystallites so that the appropriate planes will be in the correct orientation to diffract the wavelength $\lambda$ each time the Bragg condition is satisfied. Thus in X-ray diffraction each peak angle value corresponds to a certain $d$-spacing. In the wavelength-dispersive spectrometer a single crystal of known $d$-spacing is used to disperse the polychromatic beam of characteristic wavelengths coming from the sample, such that each wavelength will diffract at a discrete angle.

Figure 5 shows a schematic drawing of a typical vertical powder diffractometer system and illustrates the geometry of the system. This geometric arrangement is known as the Bragg–Brentano parafocusing system and is typified by a diverging beam from a line source F, falling onto the specimen S, being diffracted and passing through a receiving slit RS to the detector. Distances FS and SRS are equal. The amount of divergence is determined by the effective focal width of the source and the aperture of the divergence slit DS. Axial divergence is controlled by two sets of parallel plate collimators (Soller slits) SS1 and SS2 placed between focus and specimen, and specimen and scatter slit respectively. Use of the narrower divergence slit will give a smaller specimen coverage at a given diffraction angle, thus allowing the attainment of lower diffraction angles where the specimen has a larger apparent surface (thus larger values of $d$ are attainable). This is achieved, however, only at the expense of intensity loss. Choice of the divergence slit, plus its matched scatter slit, is thus governed by the angular range to be covered. The decision as to whether or not the slit size should be increased at a given angle will be determined by the available intensity. A scintillation detector is typically placed behind the scatter slit and this converts the diffracted X-ray photons into voltage pulses. These pulses may be integrated in a rate meter to give an analog signal on an x/t recorder. By synchronizing the scanning speed of the goniometer with the recorder, a plot is obtained of degrees $2\theta$ against intensity, called the diffractogram. A timer/scaler is also provided for quantitative work and this is used to obtain a measure of the integrated peak intensity of a selected line(s) from each analyte phase in the specimen. A diffracted beam monochromator may also be used in order to improve signal-to-noise characteristics.

### 5.4 Powder Cameras

The simplest device for the measurement of a powder diffraction diagram is the Debye–Scherrer powder camera. This consists of a cylindrical camera body carrying an entrance pinhole collimator and an exit beam collimator lying along the diameter of the camera. The specimen is mounted as a thin cylinder at the central axis of the camera. A piece of film is placed inside the cylindrical wall of the camera and small holes are cut in the film for the entrance and exit collimators. A beam of X-rays is directed onto the specimen via the entrance collimator and the diffracted X-rays fall onto the film. The film is then developed and laid flat for the interpretation. In order to make estimation of $2\theta$ values from the film easy, the diameter of the camera is made such that one or two mm of film corresponds to exactly $1^\circ 2\theta$. The powder camera finds great application in the analysis of very small specimens and good patterns can be obtained from only a few milligrams of specimen. The camera technique has the disadvantage that it may be rather slow and exposure times are typically in the range of 1–6 hours. In addition to the Debye–Scherrer powder camera there are also available more specialized cameras for various applications. As an example, the Guinier camera is a powder camera which incorporates a focusing monochromator and works in a transmission mode. Although the intensities are rather unreliable and it is more difficult to align than the Debye–Scherrer camera, the Guinier camera can give
6 PHASE CHARACTERIZATION BY X-RAY DIFFRACTION

6.1 Qualitative Analysis of Polycrystalline Material

Of all of the methods available to the analytical chemist only X-ray diffraction is capable of providing general purpose qualitative and quantitative information on the presence of phases (e.g. compounds) in an unknown mixture. While it is true that techniques such as differential thermal analysis will provide some information on specific phase systems, under certain circumstances such methods could not be classified as general purpose. A diffraction pattern contains a good deal of information of which three parameters are of special interest:

- the position of the diffraction maxima
- the peak intensities
- the intensity distribution as a function of diffraction angle.

The three pieces of information can, in principle, be used to identify and quantify the contents of the sample, as well as to calculate the material’s crystallite size and distribution, crystallinity, stress and strain. The ideal specimen preparation for a given experiment depends largely on the information desired. A sample which is used only for the identification of its constituents may be quite different from a sample used to measure strain, which in turn may be different from a sample used in quantitative analysis.

A diffraction pattern is characteristic of the atomic arrangement within a given phase and to this extent it acts as a fingerprint of that particular phase. Thus by use of the ICDD PDF a series of potential matches can be obtained. A complication in the application of this method for the analysis of multiphase materials is that the patterns are superimposed and consequently there may be uncertainties as to which lines belong to which phases. As shown in Figure 6, it is common practice to “reduce” the experimental pattern to a reduced pattern. This process was first carried out because of problems with storage and replication of powder patterns, and the procedure persists today.

In practice it is rather unusual to analyze specimens in which nothing at all is known. Generally one has access to information about sample history, environment, etc. and additional analytical information can be employed where available. As an example, in the routine analytical laboratory it is common to find the X-ray diffractometer and the X-ray spectrometer being used to give complementary information. Thus a more common means of identifying phases in an “unknown” mixture is to use the technique of preconceived. In this case educated guesses are made as to what phases may be present and these phases are sought first. As an example, if one were analyzing a specimen obtained by aspirating air through a filter paper, and the X-ray spectrometer indicated significant concentrations of silicon and iron, likely candidates to search for in the diffraction pattern would be SiO2, Fe2O3 and FeSiO3. In order to simplify the search procedure further the ICDD has subdivided the file of standard patterns into Mineral, Inorganic, Organic, Metals and Alloys, Common Phases, etc. XRD is an invaluable technique for qualitative phase identification but it is neither a sensitive nor a rapid means of analysis. The minimum detectable limit found by routine qualitative procedures would be of the order of several percent, compared, for example, with a few parts per million in XRF. A complete analysis would take several hours to complete, although this will of course depend to a very large extent on the experience of the analyst and the complexity of the problem in hand. The method is applicable to almost any crystalline material whether inorganic or organic.

6.2 Search Procedures

The PDF is described in section 5. Several different approaches are used to identify phases in an unknown
mixture. The first method is an analytical approach in which no basic assumptions are made about the sample being analyzed. The three strongest lines in the pattern are used to locate potential matches in the PDF index. Each time a potential candidate is found, a match is made with the complete pattern. If all lines agree, a phase confirmation is assumed and the lines for the match subtracted from the original pattern. This process is repeated until all significant lines in the pattern are identified. The second method is based on a series of guesses based in turn on preconceived ideas of what phases might be present. The two basic parameters being used in this search/match process are the “d” values which in turn have been calculated from the measured 2θ values in the diffractogram, and the relative intensities of the lines in the pattern. Whereas the “d” value can be accurately measured – perhaps with an accuracy of better than 0.5% in routine analysis, the intensities are by comparison rather unreliable and can be subject to errors, sometimes running into tens of percent.

6.3 Modern Computer-based Methods

More than 90% of all new powder diffractometers now sold in the world are automated. Many excellent computer programs are provided with these instruments to aid the diffractionist in the reduction of powder data. Unfortunately, there can be pitfalls in the use of some of these programs, especially for the newcomer to the diffraction field. A popular misconception is that automated diffractometers are easier to use than manual systems. What, in fact, is true is that automated powder diffractometers (APD) can give many hours of unattended and reliable data collection and can greatly assist in the tedious and routine tasks of data analysis, provided one is careful to apply the programs in the correct manner.

During the 1960s, as mainframe computers evolved (e.g. IBM 7094, CDC 6600, etc.) crystallographic computing was performed in a noninteractive environment, where cards were input into a program operating in a batch stream. Owing to the very high cost of computers, laboratory automation was nearly nonexistent, so these early developments can be considered as the zeroth generation of laboratory computational software. One of the first APDs was developed by Rex in the mid-1960s. However, it took the microelectronics revolution of the 1970s to initiate the general techniques which have led to today’s automated instrumentation. Although the principal thrust in the early 1970s was to develop the hardware interfaces needed to allow a computer to control a diffractometer, this work rapidly gave way to the much more serious problems of devising algorithms for the control of the instrument and the processing of the digital data.

The 1970s saw the evolution of the early laboratory computer (e.g. the Digital Equipment Corporation PDP-8, and PDP-11), and the first generation of process control software. Input to the program was first by paper tape and later by magnetic tape cassette, with programs written in low-level assembler language. Systems of this type were developed at Alfred University, Corning Glass Works and General Electric. The first commercial APD system in the USA was the Philips APD-3500 which developed from involvement in the NASA project for a Lunar Receiving Laboratory. This instrument utilized a 4000-word, 18-bit program logic controller (a forerunner of what was to become the microprocessor). Within the 4 K of core, routines were available for hardware control, data collection, data manipulation and sophisticated math – all without hardware arithmetic capability!

The second generation of laboratory software evolved on the next generation of laboratory computers (e.g. the PDP 11/34), with the introduction of floppy disks which permitted convenient use of high-level language compilers. The first of these systems was written in FORTRAN and allowed the user to conduct an interactive dialogue with the computer to set up and execute an automated experiment and analyze the data. The development of the 5 and 10 Mbyte Phoenix and Winchester disk drives, allowed the development of the third generation of software involving extensive file structures with help screens on video terminals and default files containing the users’ typical settings, rather than interactive dialogue. A fourth generation of software is currently evolving where all interactions with the user are done through a “point and click” video interface with a mouse. The trend is to eliminate all keyboard activity and convert crystallographic methods, which used to rely on the user evaluating numbers, to visual examination of graphical data.

There are essentially four elements to the automation of a diffractometer:

- the replacement of the synchronous θ : 2θ motor with a stepping motor and its associated electronics
- the replacement of a conventional scaler/timer with one which can be remotely set and read
- the conversion of the various alarms, limit switches and shutter controls to computer-readable signals
- the creation of an interface which will allow a computer to control 1 through 3.

These four items are easily obtained today by direct purchase of modules which often plug directly onto the bus of a modern minicomputer.

Today, nearly all laboratory APD systems are controlled by a personal computer. The major impact of computer automation on improving the accuracy of the measurement of diffraction angles has come from the algorithms which bring much more intelligence to the
process than has been conventionally used in manual measurements. There are two areas here which need to be considered; the first is the algorithms which control the collection of data, and the second, those which reduce the data to $d$ values and intensities. The first generation of control algorithms were principally nonoptimizing, move and count methods. Although various attempts have been made to use the computer’s decision-making capability to bring more “intelligence” to the data-collection process, the algorithms in use today continue to be nonoptimizing. The fundamental problem is the determination of the intensity threshold above background, which limits the ability to detect small peaks that could be due to trace phases in the specimen. Thus, in the limit, an intelligent algorithm would spend all of its time counting where the peaks are not present. The key hindrance to the development of intelligent data-collection software remains our inability to predict or even accurately describe the diffractometer’s background function.

6.4 Limitations Due to the Specimen

The aim of any diffraction experiment is to obtain the best possible data, within the appropriate constraints of the relevant circumstances, so that the data can be correctly interpreted and analyzed. One of the major problems in achieving this goal is the preparation of the specimen. Various methods of specimen preparation have been devised and the success of a given diffraction experiment will invariably depend on the correct choice of preparation method for the sample being analyzed and for the instrument conditions being used for the analysis. Because of the many problems associated with the form of the analyzed material, it is useful to differentiate between the sample and the specimen. The sample is generally considered to be the material submitted for analysis. It is generally assumed that the sample has been correctly taken (sampled) by the submitter to give a representative measure of the problem at hand. It is now up to the diffractionist to take an aliquot of the sample and prepare a specimen for analysis. This specimen preparation may involve a number of steps such as drying, grinding, sieving, dilution, mounting, etc. It is tacitly assumed that the analysis of the specimen represents the analysis of the sample. While this assumption is generally true, it may not always be so, and the analyst must be on his guard to ensure that all reasonable precautions are taken to avoid contamination or phase changes during the process of specimen preparation.

The biggest overall problem in specimen preparation is that due to preferred orientation. Particle and crystallite size, sample size, sample position, crystallite orientation, and absorption will affect the quality and appearance of any diffraction pattern. As a rule of thumb, the best specimen preparation methods are those that allow the analyst to obtain the desired information with the least amount of sample treatment. This is especially important in the analysis of unknown materials, pharmaceuticals and organics where the materials being analyzed may be sensitive to grinding, humidity or atmospheric environment. Extensive specimen preparation may change the sample so that the analyst is no longer analyzing the original problem. A good example is the case of hydrates and polymorphs in pharmaceutical formulations. The presence of hydrates and/or polymorphs may change the melting, solubility and blending characteristics of the formulation. In such a case the analyst must ensure that the sample preparation method does not dehydrate the sample or change the polymorphic composition. This may eliminate specimen preparation methods involving grinding, spray drying and vacuum drying and may necessitate that the sample be sealed in a controlled environment.

6.5 Quantitative Methods

Once the presence of a phase has been established in a given specimen one can, at least in principle, determine how much of that phase is present by use of the intensities of one or more diffraction lines from the phase. However, as has been pointed out previously, it may be difficult to obtain an accurate value for these intensities. The intensities of the diffraction peaks are subject to a variety of random and systematic errors and the errors fall roughly into three categories:

- Structure-dependent: that is a function of atomic size and atomic arrangement, plus some dependence on the scattering angle and temperature.
- Instrument-dependent: that is a function of diffractometer conditions, source power, slit widths, detector efficiency, etc.
- Specimen-dependent: that is a function of phase composition, specimen absorption, particle size, distribution and orientation.

For a given phase, or selection of phases, all structure-dependent terms are fixed, and in this instance have no influence on the quantitative procedure. Provided that the diffractometer terms are constant, this effect can also be ignored. Thus if one calibrates the diffractometer with a sample of the pure phase of interest and then uses the same conditions for the analysis of the same phase in an unknown mixture, only the random errors associated with a given observation of intensity have to be considered. The biggest problem in the quantitative analysis of multiphase mixtures then remains the specimen-dependent terms, and specifically those dependent upon particle size and distribution, plus effects of absorption.
The absorption effect has already been mentioned and clearly, in a multiphase mixture, different phases will absorb the diffracted photons by different amounts. As an example, the mass attenuation coefficient for Cu Kα radiation is 308 (cm² g⁻¹) for iron, but only 61 (cm² g⁻¹) for silicon. Thus iron atoms are five times more efficient than silicon atoms for absorbing Cu Kα photons. There are a variety of standard procedures for correcting for the absorption problem of which by far the most common is the use of the internal standard. In this method a standard phase is chosen which has about the same mass absorption coefficient as the analyte phase, and a weighed amount of this material is added to the unknown sample. The intensities of a line from the analyte phase and the internal-standard phase are then used to estimate the relative concentrations of internal-standard and analyte phases. The relative sensitivity of the diffractometer for these two phases is determined by a separate experiment.

The handling of particle problems is unfortunately much more complex. As has been previously stated the powder method requires a specimen which is randomly oriented since the geometry of the system requires that an equal number of crystallites be in the correct position (i.e. orientation) to diffract at any diffraction angle where the goniometer happens to be. Where particles lie in a preferred orientation there will be more particles available to diffract at the angle corresponding to this orientation, and, what is equally important, less particles available to diffract at other diffraction angles. The overall effect is to enhance some intensities and to diminish others. In other words, the intensities are now dependent upon particle distribution and orientation. Some materials, just by virtue of their crystal habit, may become preferentially oriented during sample preparation. As an example, mica, being a rather "platy" material, will prefer to stack one plate on top of another rather than take up a random orientation. The overall effect of preferred orientation can vary from insignificance to the extent where errors of the order of tens of percent can accrue in cases where they are not taken care of. Careful specimen preparation is always called for and this may include grinding, sieving, spray-drying, and a host of other techniques. The areas of application of quantitative XRD are many and varied, and hundreds of analysts are using this technique on a daily basis. Some of the more common applications would include ore and mineral analysis, quality control of rutile/anatase mixtures, retained austenite in steels, determination of phases in airborne particulates, various thin-film applications, study of catalysts and analysis of cements. The current state of the art in the quantitative analysis of multiphase materials is that accuracy of the order of a percent or so can be obtained in those cases where the particle orientation effect is either nonexistent, or has been adequately compensated for.

6.6 Limitations of the Diffraction Method

There is little doubt that the diffraction method is without parallel as a general-purpose tool for phase identification but like all analytical techniques it is not without some shortcomings. Two of these are of particular importance. The first of these is related to the chance of misinterpretation during the course of a qualitative analysis procedure. Although, in principle, a diffraction pattern is "unique", in practice there are sufficient similarities between patterns as to cause confusion. This is particularly so in the case of multiphase specimens. In addition to this there are probably in excess of two million possible unique "phases", of which only 120,000 or so are on the ICDD file as single-phase patterns. There is as a result a certain chance of a given phase not being in the file. The second problem relates to the sensitivity of the powder diffraction method. As such, the diffraction method is not comparable in sensitivity (i.e. rate of change of measured signal per change in analyte-phase concentration) to the other X-ray-based techniques. Whereas in X-ray spectrometry one can obtain detection limits in the low parts per million region, the powder method has difficulty in identifying several tenths of one percent. To this extent it is less sensitive than the fluorescence method by about three orders of magnitude.

7 FUTURE TRENDS FOR X-RAY DIFFRACTION AND FLUORESCENCE

7.1 Analysis of Small Specimens and Thin Films

Conventional XRF spectrometers are generally designed to handle rather large specimens with surface areas of the order of several square centimeters, and problems occur where the sample to be analyzed is limited in size. The modern wavelength-dispersive system is especially inflexible in the area of sample handling, mainly because of geometric constraints arising from the need for close coupling of the sample to X-ray tube distance, and the need to use an airlock of some kind to bring the sample into the working vacuum. The sample to be analyzed is typically placed inside a cup of fixed external dimensions that is, in turn, placed in the carousel. This presentation system places constraints not only on the maximum dimensions of the sample cup, but also on the size and shape of samples that can be placed into the cup itself. Primary source energy-dispersive systems do not require the same high degree of focusing, and to this extent are more easily applicable to any sample shape or size,
provided that the specimen will fit into the radiation protected chamber. In some instances the spectrometer can even be brought to the object to be analyzed. Because of this flexibility, the analysis of oddly shaped specimens have been almost exclusively the purview of the energy-dispersive systems. In the case of secondary target energy-dispersive systems, while the geometric constraints are still less severe than the wavelength system, they are much more critical than in the case of primary systems. Where practicable, the best solution for the handling of limited amounts of material is invariably found in one of the specialized spectrometer systems.

One of the major problems that inhibits the obtaining of good detection limits in small samples is the high background due to scatter from the sample substrate support material. The suggestion to overcome this problem by using total reflection of the primary beam was made as long ago as 1971,27 the technique being referred to as total reflection X-ray fluorescence (TRXRF) spectrometry. Unfortunately the absence of suitable instrumentation prevented real progress being made until the late 1970s.28,29 The TRXRF method is essentially an energy-dispersive technique in which the Si(Li) detector is placed close to (about 5 mm), and directly above, the sample. Primary radiation enters the sample at a glancing angle of a few seconds of arc. The sample itself is typically presented as a thin film on the optically flat surface of a quartz plate. Here, a beam of radiation from a sealed X-ray tube passes through a fixed aperture onto a pair of reflectors that are placed very close to each other. Scattered radiation passes through the first aperture to impinge on the sample at a very low glancing angle. Because the primary radiation enters the sample at an angle barely less than the critical angle for total reflection, this radiation barely penetrates the substrate media; thus scatter and fluorescence from the substrate are minimal. Because the background is so low, picogram amounts can be measured or concentrations in the range of a few tenths of a ppb can be obtained without recourse to preconcentration.30 Similar parallel-beam thin-film methods are finding increasing use in powder diffraction.

7.2 Impact of the Synchrotron
The availability of intense, linearly polarized synchrotron radiation beams31 has prompted workers in the fields of XRF32 to explore what the source has to offer over more conventional excitation media. An exciting new field developed in the early 1980s called synchrotron source X-ray fluorescence (SSXRF). In the synchrotron, electrons with kinetic energies of the order of several billion electron volts (typically 3 GeV at this time), orbit in a high-vacuum tube between the poles of a strong (about 10000 Gauss) magnets. A vertical field accelerates the electrons horizontally, causing the emission of synchrotron radiation. Thus synchrotron source radiation can be considered as magnetic bremsstrahlung in contrast to normal electronic bremsstrahlung produced when electrons are decelerated by the electrons of an atom. It has been found that, because the primary source of radiation is so intense, it is possible to use a high degree of monochromatization between source and specimen, giving a source that is wavelength (and, therefore, energy) tunable, as well as being highly monochromatic. There are several different excitation modes that can be used using SSXRF including: direct excitation with continuum, excitation with absorber-modified continuum, excitation with source crystal monochromatized continuum, excitation with source radiation scattered by a mirror, and reflection and transmission modes. The intensity of the synchrotron beam is probably four to five orders of magnitude greater than the conventional bremsstrahlung source sealed X-ray tubes. This, in combination with its energy tunability and polarization in the plane of the synchrotron ring, allows very rapid bulk analyse to be obtained on small areas. Because the synchrotron beam has such a high intensity and small divergence, it is possible to use it as a microprobe of high spatial resolution (about 10 μm). Absolute limits of detection around 10−14 pg have been reported using such an arrangement.33 SSXRF has also been used in combination with TRXRF. Very high signal/background ratios have been obtained employing this arrangement for the analysis of small quantities of aqueous solutions dried on the reflector, with detection limits of <1 ppb or 1 pg. Additional advantages accrue because synchrotron radiation is highly polarized and background due to scatter can be greatly reduced by placing the detector at 90° to the path of the incident beam and in the plane of polarization. A disadvantage of the SSXRF technique is that the source intensity decreases with time, but this can be overcome by bracketing analytical measurements between source standards and/or by continuously monitoring the primary beam.

Absorption Techniques in X-ray Spectrometry

Jun Kawai
Kyoto University, Kyoto, Japan

1 INTRODUCTION

X-rays are absorbed in matter and the energy of the X-rays is converted into the kinetic energy of photoelectrons, Auger electrons, secondary electrons, or fluorescent X-rays. The incident X-ray energy finally becomes the thermal energy of the absorber.

The amount of energy absorbed by a matter is usually estimated by a transmission method, but can also be estimated by measuring these secondary phenomena, such as photoelectrons, Auger electrons, secondary electrons, fluorescent X-rays, thermal radiation, and drain electric currents. The X-ray intensity of wavelength λ before (I₀) and after (I) the transmission of a thin film of thickness d is expressed by I(λ) = I₀(λ)exp[−(μ(λ)/ρ)d], where μ(λ) and ρ are the mass absorption coefficient and mass density, respectively, of the ith element in the thin film and their dimensions are [cm² g⁻¹] and [g cm⁻³], respectively.(1–7) The mass absorption coefficient μ of a specimen which contains n kinds of elements is expressed by μ = μ₁(λ)W₁ + μ₂(λ)W₂ + ⋯ + μₙ(λ)Wₙ, where W₁, W₂, ⋯, Wₙ are the weight fractions of element 1, 2, ⋯, n in the specimen. The wavelength dependence of the absorption coefficient μ(λ) is clarified when log μ(λ) is plotted against log λ as shown in Figure 1; μ(λ) values are taken from Henke et al.(8) in this plot. Henke et al.(8) tabulated μ(λ) from Z = 1 to 92 at energy from 50 eV to 30 keV.

The plot of the mass absorption coefficients of matter against the incident X-ray energy or wavelength is called an X-ray absorption spectrum (XAS), where we find some jumps at particular X-ray energy, corresponding to K, L₁, L₂, L₃, ⋯ electron shell binding energies as shown in

X-ray absorbance depends on the wavelength of the X-rays, atomic number, chemical environment, and concentration of analyte. X-ray absorption spectrometry is a technique for analyzing the chemical environment of an element in an unknown material. This method is closely related to photoelectron spectroscopy, Auger electron spectroscopy, and X-ray fluorescence spectroscopy.

Chemical information in the chemical shift and line shape of XANES (X-ray absorption near-edge structure) spectra is described. The history and theory of EXAFS (extended X-ray absorption fine structure) are discussed in relation to other experimental techniques. Data analysis methods, databases, software packages, instrumentation, and synchrotron radiation facilities for X-ray absorption analysis are overviewed. Alternative methods such as electron energy loss spectroscopy (EELS), self-absorption effect, extended X-ray emission fine structure (EXEFS), X-ray Raman scattering, diffraction anomalous fine structure (DAFS), β-environment fine structure (BEFS), and inverse photoemission spectroscopy (IPES) are also described.

where $\lambda$ is the X-ray wavelength, $Z$ is the atomic number, and $K$ and $s$ are constants for a spectral series. The absorption coefficient is crudely proportional to $Z^4$, except for the edge jumps. The energy at which the jump is observed is called the threshold energy, but the definition of the threshold is not exact, because it corresponds to the transition from a core orbital to the lowest unoccupied orbital. The ionization limit is a few or a few tens of electron-volts higher than the edge energy.

The mass per unit area is given by $\rho d$, where $\rho$ is the mass density. The linear absorption coefficient $\mu_l$ is defined by $\mu_l = \rho \mu$, and its dimension is [cm$^{-1}$]. The X-ray attenuation length $l/\mu_l$ is the length at which the X-ray intensity becomes 1/e after traveling in matter. The attenuation length of Cu Kα1 X-rays (8047.8 eV) is 79 $\mu$m in aluminum, 4.2 $\mu$m in iron, 24 $\mu$m in copper, and 3.9 $\mu$m in lead. The attenuation length of Al Kα X-rays (1486.7 eV) is 9.2 $\mu$m in aluminum and 0.4 $\mu$m in iron. The intensity of X-rays emitted by a copper target X-ray tube is, however, attenuated by only half after transmission through 2-mm-thick aluminum, but depends on the applied power on the X-ray tube, because the X-rays emitted from an X-ray tube are not monochromatic. Thus it should be noted that the X-ray shielding thickness for safety cannot be determined only from the monochromatic X-ray attenuation length.

The linear absorption coefficient can otherwise be expressed as $\mu_l = 4\pi \beta / \lambda$, where $\lambda$ is the X-ray wavelength and $\beta$ the imaginary part of the complex refractive index.

state has a total angular momentum $\frac{1}{2}$, and the subscript $\frac{1}{2}$ is usually omitted. The multiplicity of the state, which is crudely proportional to the spectral intensity, is $2j + 1$. The jump is called the absorption edge, and the wavelength is highly correlated with the atomic number similarly to Moseley’s law in X-ray emission spectra. Moseley’s law in emission spectra is expressed as Equation (1):

$$\frac{1}{\sqrt{\lambda}} = K(Z - s)$$ (1)

where $\lambda$ is the X-ray wavelength, $Z$ is the atomic number, and $K$ and $s$ are constants for a spectral series. The absorption coefficient is crudely proportional to $Z^4\lambda^3$ except for the edge jumps. The energy at which the jump is observed is called the threshold energy, but the definition of the threshold is not exact, because it corresponds to the transition from a core orbital to the lowest unoccupied orbital. The ionization limit is a few or a few tens of electron-volts higher than the edge energy.

The mass per unit area is given by $\rho d$, where $\rho$ is the mass density. The linear absorption coefficient $\mu_l$ is defined by $\mu_l = \rho \mu$, and its dimension is [cm$^{-1}$]. The X-ray attenuation length $l/\mu_l$ is the length at which the X-ray intensity becomes 1/e after traveling in matter. The attenuation length of Cu Kα1 X-rays (8047.8 eV) is 79 $\mu$m in aluminum, 4.2 $\mu$m in iron, 24 $\mu$m in copper, and 3.9 $\mu$m in lead. The attenuation length of Al Kα X-rays (1486.7 eV) is 9.2 $\mu$m in aluminum and 0.4 $\mu$m in iron. The intensity of X-rays emitted by a copper target X-ray tube is, however, attenuated by only half after transmission through 2-mm-thick aluminum, but depends on the applied power on the X-ray tube, because the X-rays emitted from an X-ray tube are not monochromatic. Thus it should be noted that the X-ray shielding thickness for safety cannot be determined only from the monochromatic X-ray attenuation length.

The linear absorption coefficient can otherwise be expressed as $\mu_l = 4\pi \beta / \lambda$, where $\lambda$ is the X-ray wavelength and $\beta$ the imaginary part of the complex refractive index.
(n = 1 − δ − iβ).\(^{(7)}\) The atomic form factor, \(f = f_1 + if_2\), which is used in the analysis of X-ray diffraction, is related to the refractive index (Equations 2 and 3):

\[
\delta = \frac{N r_0 \lambda^2 f_1}{2\pi} \quad (2)
\]

\[
\beta = \frac{N r_0 \lambda^2 f_2}{2\pi} \quad (3)
\]

where \(N\) is the number of atoms in unit volume and \(r_0 = e^2/(mc^2) = 2.818 \times 10^{-13}\) cm is the classical electron radius (\(e\) the electron charge, \(m\) the mass, and \(c\) the speed of light). The real part \(f_1\) is the Fourier transform of the electron density distribution in an atom. The relation between the absorption coefficient and atomic form factor is used in DAFS described below.

The mass absorption coefficient is the sum of two effects: photoelectric absorption and scattering of X-rays. The photoelectric absorption is the ionization of an inner-shell electron. Therefore, the absorption coefficient due to the photoelectric part can be calculated by the photoionization cross-section.\(^{(8)}\) The scattering part is due to the Rayleigh (coherent) and Compton (inelastic) scattering of X-rays, but X-ray absorption spectra are often taken as if they represent only the photoelectric absorption effect, although the experimental spectra contain both effects.

The mass absorption coefficients or physically equivalent parameters\(^{(9,10)}\) and the absorption edge energy or wavelength\(^{(14,15)}\) can be found in the literature. The value of the absorption edge energy is close to the electron binding energy, which is used in electron spectroscopy, ESCA (electron spectroscopy for chemical analysis) or XPS (X-ray photoelectron (photoemission) spectroscopy).\(^{(16,17)}\) The absorption edge jump is not exactly the same as the electron binding energy, because the absorption edge energy corresponds to the excitation of core electrons into the lowest unoccupied molecular orbital (LUMO) in the molecular orbital picture, or Rydberg state in the atomic orbital picture. The Rydberg state and continuum state threshold are clearly seen in rare gas X-ray absorption spectra but are not clear for condensed matter. The difference between the vacuum level and Fermi energy, which defines the highest energy of electrons in a conduction band, is called the work function, \(\Phi\). This is another source of the difference between the electron binding energy observed in XPS and the absorption edge. The photoionization cross-sections\(^{(18,19)}\) and the electron binding energies\(^{(20,21)}\) can be found in the literature. The relation between the electron photoionization cross-section (barns) and mass absorption coefficient is simple when the angular dependence is averaged.\(^{(11)}\)

Absorption techniques in X-ray spectrometry are used to measure the X-ray absorption spectra using various methods described below, and to analyze the obtained spectral line shapes to obtain information on the element, oxidation state, concentration, atomic distance, coordination number, surface geometry, and reaction on solid surfaces, catalysts, or electrodes.

### 2 Acronyms and a Brief History

The mass absorption coefficient plotted against the X-ray energy is called the XAS. The X-ray absorption spectra of condensed matter near the threshold energy have fine structures as shown in Figure 2. Fine structures are sometimes observable at energies less than the threshold energy, and are called the pre-edge structure (Figure 3).\(^{(22)}\) These fine structures are called the XANES, usually pronounced as “zaenz”. The absorption fine structure will extend up to 1000 eV above the threshold energy, and thus it is called the EXAFS,\(^{(23–26)}\) pronounced “eksafs”. XANES is restricted from the threshold to ca. 50 eV above (this energy approximately corresponds to \(KR = 2\pi\), where \(k\) is the ejected photoelectron momentum and \(R\) the nearest-neighbor atomic...
X-RAY SPECTROMETRY

Figure 5 Schematic illustration of electron wave propagating and scattering in a solid. (Reproduced by permission from Udagawa.)

distance as shown in Figure 4. The momentum of the photoelectron is \( k = \sqrt{2m(E - E_0)} \), where \( E \) is the photoelectron kinetic energy, \( E_0 \) the threshold energy, \( m \) the electron mass, and \( h \) Planck’s constant. The photoelectron matter wave in a condensed system propagates as a spherical wave and forms a standing wave as shown in Figure 5. Recently, XANES has come to be called near-edge X-ray absorption fine structure (NEXAFS), pronounced “nexasfs”. All the fine structures including NEXAFS and EXAFS are grouped into the term X-ray absorption fine structure (XAFS), pronounced “zafs”.

The history of the development of the understanding and application of XAFS has an interesting feature, as stated by Lytle et al., Shiraiwa, Stern, and Lytle. Barkla (after Stern) or de Broglie (after Lytle) firstly found the X-ray absorption edge. Although XANES was found for both solids and gases, EXAFS was found only for condensed matter such as molecules, solids and liquids. EXAFS was first reported by Fricke in 1920 and was theoretically interpreted by Kossel. He explained that the fine structure was due to the excitation of inner-shell electrons to an unoccupied level. This theory was valid for XANES, and thus XANES was called the Kossel structure. The Kossel theory was called short-range order (SRO) theory, because the electronic structures of unoccupied levels are mostly determined by orbital hybridization between the center atom and the nearest-neighbor atoms. On the other hand, Kronig explained that fine structure was the result of the diffraction of photoelectrons as a matter wave when moving in a conduction band of a solid. The electron matter wave travels in a solid when the wavelength of an electron \( \lambda_e \) does not satisfy the Bragg condition, \( 2d \sin \theta = n\lambda_e \). When the Bragg condition is satisfied, then the electrons are scattered and leave the solid. His theory explained EXAFS and thus EXAFS was called the Kronig structure. His theory was called the long-range order (LRO) theory because the band structure is determined by the long-range periodic boundary conditions. Hayasi considered that the electron waves that satisfied the Bragg condition form a standing wave in a solid, and thus the electron transition from an inner orbital to a standing wave state yields a maximum of X-ray absorption. Shiraiwa et al. and Kozenkov improved the SRO theory to explain the EXAFS, but their method needed to solve a Schrödinger equation to obtain the EXAFS. Sayers et al. proposed a Fourier transform method to obtain local structural information on condensed systems. Owing to their Fourier analysis, we do not need to solve the Schrödinger equation directly to obtain the local structure of matter. EXAFS had at that time great potential to be developed as a powerful method of analyzing the local structure of matter. The inelastic mean free path (IMFP) of a photoelectron is usually 2 nm. When the photoelectron is scattered inelastically, the coherence is forgotten. The coherent length, i.e. the length within which the electron matter waves emitted from a single source can interfere with each other, is an important length to apply in the EXAFS method to analyze a condensed system. When the IMFP is included in the LRO theory, it is equivalent to the SRO theory.
The XAFS represents the unoccupied electron density of states for atoms, molecules, solids, or liquids. One of the inner shell electrons, say a 1s electron, is excited into a discrete or continuum unoccupied state by the incident X-ray photon. The transition probability from the 1s to the unoccupied state equals the X-ray absorption intensity (only the photoelectric part is considered here), and thus the plot of the intensity against the incident X-ray energy is the XAS of a specimen. XANES is chiefly due to the transition from the inner shell to the unoccupied discrete level (Figure 6), and EXAFS is to the unoccupied continuum level.

3 X-RAY ABSORPTION NEAR-EDGE STRUCTURE

3.1 Chemical Shift and Line Shape

The XANES spectra show both the line shape modification and chemical shift\(^{(39)}\) of the absorption edge or peak. Figure 7\(^{(40)}\) shows typical examples for the S K edge for \(\text{Na}_2\text{SO}_4\), \(\text{Na}_2\text{SO}_3\), and \(\text{Na}_2\text{S}_2\text{O}_3\). The sharp and prominent absorption peak shown in Figure 7\(^{(40)}\) is called the “white line”. This is because in the early days of X-ray experiments a white line developed on the X-ray film was observed. The white line for insulators is usually sharper than that for metals, because it corresponds to a 1s \(\rightarrow\) \(\pi^*\) electron transition, where the asterisk denotes an unoccupied antibonding orbital. The \(\pi^*\) state is usually a sharply localized state. The metal has a broad conduction band, and thus the absorption spectra show an edge jump but not a white line.

The white line energy plotted against the oxidation number of sulfur is shown in Figure 8\(^{(41)}\). The source of the chemical shift is both the unoccupied level shift and core level shift. The range of the unoccupied level shift ranges from the Fermi level (\(=0\) eV) to the band gap energy (\(\approx\) few electron-volts). The core level shift is due to the screening of core electrons by valence electrons; if the atom is negatively charged then the core level is shifted to a shallower binding energy, and if an atom is positively charged then it is shifted to a deeper energy. The source of the core level shift is the same as that of an ESCA chemical shift.

In Figure 9\(^{(42)}\) is shown another example of a chemical shift of the absorption edge for Al compounds: Al metal, AlN, and four- and six-fold coordinated oxides. The Al–O distance of four-fold coordinated aluminum oxide (0.17 nm) is shorter than that of six-fold coordinated oxide (0.19 nm), because the oxygen ions interfere with each other and cannot be close to the Al atom for six-fold coordinated oxide. Thus the orbital hybridization of four-fold coordinated oxide is stronger than that of six-fold coordinated oxide, and consequently the six-fold form is
ionic and the four-fold form is covalent. The effective positive charge of six-fold coordinated Al$^{3+}$ is larger than that of four-fold coordinated oxide. The chemical shift of six-fold coordinated oxide is larger than that of four-fold coordinated oxide. The shift is strongly correlated to Pauling's electronegativity\(^{(43)}\) of the neighboring atom, because the electronegativity determines the effective charge of the ion.

The unoccupied discrete level is composed of Rydberg states in the atomic picture, $\pi^*$ and $\sigma^*$ orbitals in the molecular-orbital picture (the asterisk denotes an antibonding molecular orbital), or conduction bands in crystals. The $\sigma^*$ transition, which is formed in a potential well of neighboring atomic potentials, is called the shape resonance (Figure 4).

While the $1s \rightarrow \pi^*$ transition is a sharp white line, the $1s \rightarrow \sigma^*$ transition usually results in a broad and weak hump at higher energy\(^{(44)}\) which is called the shape resonance. The term shape resonance is used in the field of atomic spectra. The excited state or ionized state is bound in a potential well, because of the centrifugal force potential of a high angular momentum orbital such as an $f$ orbital, or surrounding potential such as F in SF$_6$. However, as shown schematically in Figure 4, such a surrounding potential does not have sufficient height to enclose the electron, but a weak resonance is observable. This is the origin of the term shape resonance.

The pre-edge structure shown in Figure 3 above is observed for the K edge of transition metal compounds whose local symmetry around the X-ray absorbing atom is T$_d$ (tetrahedral). On the other hand, it is not observable for locally O$_6$ (octahedral) symmetry solids. This pre-edge is sometimes said to be an electric quadrupole transition from 1s to 3d, whereas ordinary optical absorption is the electric dipole transition (1s $\rightarrow$ 2p or 2p $\rightarrow$ 3s, 3d). The quadrupole transition probability is, however, very weak, as shown in Table 2, where the probability is calculated by the Dirac–Fock method.\(^{(45)}\) The origin of such a strong absorption as shown in Figure 3 is due to the electric dipole transition. The unoccupied p orbitals strongly hybridize with the d band for tetrahedral symmetry compounds based on the group theory as shown in Table 3,\(^{(46)}\) where both p and d orbitals belong to the t$_2$ orbital. Thus the electric dipole transition is strongly observed at the energy of an empty d band. On the other

The chemical shifts of reference samples are measured and plotted against the electronegativity, and then the neighboring atom type is estimated for an unknown material from the chemical shift of the absorption edge.

After the discovery of high-temperature superconductors, the understanding of the electron correlation effect of transition metal compounds and rare earth compounds has been greatly improved by the study of XPS. Consequently, the understanding of the correlation effect, i.e. how the hole left in the final state of photoionization interacts with d holes in transition metal compounds, has developed substantially. Many reports have been published concerning the electron correlation effect on the XANES line shape of complicated materials.

Mixed-valence rare earth compounds are clearly observed by the measurement of XANES, as shown in Figure 11, but the intensity ratio sometimes does not directly represent the mixed-valence components because of a dynamic electron transfer, i.e. correlation effect, due to the core hole screening. The peak decomposition of XANES spectra into Eu$^{2+}$ and Eu$^{3+}$, as shown in Figure 11, yields a rough estimate of the mixed-valence state. However, the core hole created by the X-ray absorption rearranges the valence electrons and thus the peak intensity does not always represent the exact...
portion of the Eu$^{3+}$ and Eu$^{2+}$ states before the X-ray is absorbed.

3.2 Calculation Method for X-ray Absorption

Near-edge Structure Spectra

The electronic states of photoelectrons whose kinetic energy is from a few electron-volts to a few tens of electron-volts are treated as conduction electrons in a conduction band. Thus a multiple scattering (MS) method or Green’s function method, which has been used to calculate the electronic structure of conduction electrons near the Fermi energy in metals, is applicable to calculate the XANES of materials. The line shape of a XANES spectrum represents the partial and local electron density of states of the X-ray absorbing atom. Hence any kinds of electronic structure calculations other than the MS theory, such as the LCAO-MO (molecular orbital derived from a linear combination of atomic orbitals) method or the APW (augmented plane wave) method, are also applicable to interpret the near-edge fine structure. One of the most popular methods for calculating XANES spectra is the MS theory.

In the MS theory, a sphere of radius $r_i$ centered at the $i$th atom is considered, and the solid is divided by spheres. A spherically symmetric atomic potential $V(r)$ is put inside each sphere and the potential equals zero or constant outside the spheres. This is called the muffin-tin (MT) potential. The wave function in the solid is expressed as the overlap of spherical Bessel functions (radial part of the wave function) multiplied by the spherical harmonic functions (angular part of the wave function).

The wave function $\psi(r)$ of a photoionized electron is scattered by an atomic potential $V(r)$ near the ionized atom, and finally it becomes itself after being scattered many times (Equation 4)

$$\psi(r) = \frac{1}{4\pi} \exp(ik|r-r'|) \frac{V(r')\psi(r') \, dr'}{|r-r'|}$$

where $k^2 = \varepsilon$ is the kinetic energy of a photoelectron and $k$ is real for $\varepsilon > 0$ (photoionized electron), $\exp(ik|r-r'|)/(r-r')$ represents a spherically expanding wave, and $V(r)$ is the MT potential. This method is called the MS method, Green’s function method, or Korringa–Kohn–Rostker (KKR) method. The KKR method is only exact for solids that have translational symmetry, or periodic boundary conditions. Small clusters, molecules, amorphous or surface adsorbates have a lower symmetry, and it is difficult to apply directly the KKR method. Thus the cluster calculation method was proposed by Johnson and was called the multiple scattering $X\alpha$ (MS-$X\alpha$) method, because Slater’s $X\alpha$ exchange potential is used in place of the Hartree–Fock (HF) exchange integral. The $X\alpha$ method is also called the Hartree–Fock–Slater (HFS) method, and recently it has been developed as a local density approximation (LDA) theory. The calculation method for XANES spectra is a modified MS-$X\alpha$ method. In another way, the MS method is the expansion of the wave function of positive energy by an infinite sum of the spherically outgoing and incoming scattering waves. The electrons excited into the continuum level have a wave function of a standing wave formed by the infinite number of incoming and outgoing spherically traveling waves. That is to say, a wave whose intensity is $V(r')\psi(r')$ coming from every point $r'$ in space is synthesized and forms a wave $\psi(r)$ at point $r$. This method produces a wave function similar to the APW method, which is an appropriate method to calculate a metallic band structure, but APW requires a greater number of basis functions than the MS method.

The wave function at point $r$ is the sum of all the scattered waves multiplied by the phase factor. The LCAO-MO method is another choice for calculating the electronic structures of solid or molecules, and is thus applicable to the calculation of XANES spectra. An atomic calculation yields a satisfactory agreement between experiment and theory, as shown in Figure 12, after the inclusion of the perturbation of crystal field splittings. Bragg reflection of electrons in a crystal reproduces a rough XANES spectrum.

4 THEORY OF EXTENDED X-RAY ABSORPTION FINE STRUCTURE

4.1 Single Scattering Theory

Whereas MS of photoelectrons in a solid is a good approximation to treat XANES, because the electron kinetic energy of the EXAFS region is very high, single scattering is a good approximation to EXAFS except for...
special cases. The wave function $\phi_k(r)$ of a photoelectron scattered by a single atom is asymptotically expressed by Equation (5):

$$\phi_k(r) \longrightarrow \exp(ikz) + \frac{f(\vartheta)}{r} \exp(ikr)$$ (5)

where $f(\vartheta)$ is the scattering amplitude and $\vartheta$ is the scattering angle ($\vartheta = 0^\circ$ for forward scattering and $\vartheta = 180^\circ$ for backscattering). The scattering amplitude of an electron of velocity $v$ scattered by an atom of atomic number $Z$ is expressed by the first Born approximation (Equation 6):

$$f(\vartheta) = \frac{e^2}{2mv} [Z - A(\vartheta)] \frac{1}{\sin^2(\vartheta/2)}$$ (6)

where $e$ and $m$ are the charge and the mass of an electron, respectively, and $A(\vartheta)$ is the atomic structure factor for X-rays, given by Equation (7):

$$A(\vartheta) = 4\pi \frac{\sin kr}{kr} \rho(r)^2 dr$$ (7)

where $k = (4\pi mv/h) \sin(\vartheta/2)$ is the change in electron momentum before and after the scattering and $\rho(r)$ is the charge distribution in an atom. The forward scattering amplitude crudely depends on the atomic number in a way such that (Equation 8)

$$f(0^\circ) = \frac{1}{3} \int_0^\infty 4\pi \rho(r)r^4 dr = \frac{1}{3} Z(r^2)$$ (8)

in atomic units, because (Equation 9): $Z = \frac{1}{3} \int_0^\infty 4\pi r^2 \rho(r) dr$ (9)

where $\langle \rangle$ denotes an average. The calculated scattering amplitude is shown in Figure 13. (62)

The EXAFS is expressed by Equation (10): $\chi(k) = -\sum_j \frac{N_j}{kR_j} f_j(k, \pi) \exp(-2\sigma_j^2 k^2) \sin[2kR_j + \phi_j(k)]$ (10)

where $k = \sqrt{2m(hv - E_0)/h}$ is the photoelectron wave vector, $N_j$ is the number of nearest neighbors, $f_j(k, \pi)$ is the backscattering amplitude, and $R_j$ is the distance from the center atom. The exponential term contains the Debye–Waller-like vibrational effect and dumping. The dumping due to the finite coherent length of the photoelectron, $\exp[-2R_j/\lambda(k)],$ is multiplied for a more exact expression. The Debye–Waller factor contains both effects of thermal vibration and geometric randomness. The oscillating part of the EXAFS equation, $-\sin 2kR/(kR)^2,$ if plotted as a function of $kR,$ is the EXAFS oscillation.

The EXAFS oscillation amplitude is larger when the atomic number of neighboring elements is higher. For example, the Si K edge EXAFS oscillation amplitude of Si is stronger than that of SiO₂, because the atomic number of Si is higher than that of O. The white line of SiO₂ is sharper and stronger than that of Si. Hence the EXAFS oscillation and the white line intensity do not directly indicate the concentration of the atom in the analyte. However, the edge jump is a good measure of concentration, and the measurement of edge jump could determine the concentration without a working curve, as shown in Table 5. (63)

The effect of thermal vibration on the line shape of X-ray absorption spectra is shown schematically in Figure 14. (44) This is the line in the XANES region. Similarly, the EXAFS oscillation becomes unclear owing to thermal vibration. As the atomic number becomes

higher, the core hole lifetime becomes shorter. A shorter lifetime of the inner shell level indicates that the energy of the inner shell becomes vague because of Heisenberg’s uncertainty principle. Consequently, the EXAFS oscillation of the K spectrum for higher atomic number elements is not clear compared with that of the L edge spectrum of the same element.

The IMFP of photoelectrons is a function of kinetic energy for a particular material, as shown in Figure 15. It is 1–2 nm for the usual EXAFS experiments. Hence the photoelectron is only coherent within a few nanometers, and it probes the local structure within the IMFP. Thus 1–2 nm regularity, usually up to the next-nearest neighbors, in the structure is sufficient for the EXAFS oscillation to emerge.

4.2 Relation to Other Techniques (X-ray Photoelectron Diffraction, Low-energy Electron Diffraction, X-ray Fluorescence Holography)

X-ray photoelectron diffraction (XPD) is used to study the local structure of surfaces. The photoelectron intensity as a function of detected polar and azimuthal angles is measured in this technique. The photoelectron intensity is anisotropic in its detection angle. This effect is due to photoelectron diffraction, but roughly speaking it is due to the photoelectron’s forward scattering by the nearest-neighbor atoms around the photoelectron-emitting atom. XPD uses forward scattering of photoelectrons; EXAFS uses backscattering of photoelectrons.

Recently XPD has been treated as photoelectron holography (PEH). The intensity distribution of the photoelectrons of a single crystal is measured and Fourier transformed, and then a local atomic structure of the single crystal near the photoelectron-emitting atom can be constructed. The phase shift of electron waves scattered by a neighboring atom makes the analysis of the Fourier transform for PEH complicated. The angular distribution of the X-ray fluorescence intensity is measured and the Fourier transform of the angular distribution reconstructs the crystal image. This is called X-ray fluorescence holography (XFH). XFH is free from the phase shift problem, but this method is bulk sensitive, whereas XPD and PEH are surface sensitive.

Low-energy electron diffraction (LEED) is a surface crystallography experimental method where electrons of a few hundred electron-volts impinge on a single crystal and a diffracted electron pattern is observed. The penetration depth of these energy electrons is a few nanometers, hence this method is surface sensitive. Electron diffraction requires a periodic structure of at least 10 nm on the surface, hence the LEED method cannot probe the structure clusters of a few nanometers on a surface.

5 DATA ANALYSIS AND SOFTWARE PACKAGES FOR X-RAY ABSORPTION FINE STRUCTURE

The measured (Figure 16a) X-ray absorption spectral energy is converted into photoelectron momentum. The smooth background \( \mu_0(E) \), which means an isolated atom absorption coefficient, is subtracted from the observed

This is the EXAFS oscillation. If we want to enlarge the oscillation for a larger $k$ region, we sometimes plot $k^2 \chi(k)$ or $k^2 \chi(k)$ in place of $\chi(k)$ as shown in Figure 16(b). \(^{(69)}\)

Figure 17 Schematic illustration of diatomic molecule (full and open circles) adsorbed on a four-fold coordinated site of metal substrate (hatched circles). When the incident X-ray beam electric vector is parallel to the diatomic molecular axis, the absorption spectrum of the molecule is obtained (a strong white line due to an insulating compound is observed). When the incident X-ray beam electric vector is perpendicular to the molecular axis, information on the metallic bond between the adsorbed atom and the substrate metal is obtained. (Reproduced by permission from J. Stöhr, ‘Geometry and Bond Lengths of Chemisorbed Atoms and Molecules: NEXAFS and SEXAFS’, Z. Phys. B: Condens. Matter, 61, 439–445 (1985). © 1985 Springer-Verlag.)

\[ \chi(k) = \frac{\mu(E) - \mu_0(E)}{\mu_0(E)} \]  \hspace{1cm} (11)
Then this is Fourier transformed as shown in Figure 16(c), and a radial distribution function is obtained. To obtain the coordination geometry, measurement of the polarization-dependent EXAFS oscillation is important, as shown in Figure 17(a) and (b). An example of $K$ edge spectra of $\text{CS}_2$ on a Cu(111) surface is shown in Figure 18. A spline function or higher order polynomial determines the smooth background. Theoretically, the smooth background has a shape of $\tan^{-1}\theta$ at the threshold, because the discrete absorption line shape is a Lorentzian function and its sum in a Rydberg series becomes $\tan^{-1}\theta$ as shown in Figure 18.

An incident X-ray beam forms a standing wave in a large-sized single crystal. In this case, additional fine structure, the 1985-eV structure in Figure 19, for example, depending on the incident angle of X-rays, is observable. The standing wave profile is sensitive to the location of impurity atoms in a crystal, i.e. which site in the lattice. The use of standing waves is one of the surface analysis methods, but sometimes interferes with obtaining $\chi(k)$, as shown in Figure 19.

Another effect interfering with the observation of $\chi(k)$ is the multiple ionization effect. The effect of an additional one or two electrons ionized from outer shell(s) is not negligibly small. The double ionization probability is sometimes more than 30% of single K shell ionization. This is a source of error in EXAFS analysis.

EXAFS Fourier analysis is sometimes not easy when additional peaks such as multiple ionization, standing wave structure, and impurity peaks originating from the analyte, X-ray source, or X-ray optics emerge. Data analysis methods have been developed and several standard computer programs are now available.

FEFF is the most popular program that is used by EXAFS users. The EXAFS analysis program is not difficult to code, and a laboratory that studies EXAFS may have its own program, but not always published. Some of the programs listed in Table 6 can be downloaded from Web sites.

6 INSTRUMENTATION

6.1 Laboratory Extended X-ray Absorption Fine Structure

To measure the X-ray absorption spectra, a strong X-ray source of continuous energy is required, such as white radiation from an X-ray tube or synchrotron radiation (SR). A metallic wheel is rotated in vacuum and a high electric potential is applied between the wheel and a filament. Thermal electrons are emitted from the filament and bombard the wheel target. Water flows inside the wheel to cool it against heating by the electron bombardment. To eliminate the heating, the wheel is rotated. Therefore, this type of rotating anode X-ray tube produces one order of magnitude stronger X-rays than the ordinary sealed X-ray tubes. The electron deceleration at the metal target converts the electron kinetic energy into X-ray energy. The X-rays thus produced are continuum X-rays in addition to characteristic X-rays and the maximum energy is the acceleration electric potential applied. The X-rays from the X-ray tube are then monochromated by a crystal monochromator using the Bragg diffraction condition. Then the monochromatic X-rays are incident on the specimen as shown in Figure 20. (74) Sometimes, to compensate for the weak source intensity, a position-sensitive proportional counter is used as shown in Figure 21. (75) However, the very simple experimental set-up shown in Figure 22 (76) is sometimes used.

6.2 Synchrotron Radiation Extended X-ray Absorption Fine Structure

Recently, SR has frequently been used as an X-ray source. Synchrotron is the name of an electron (or positron) accelerator made of an ultrahigh vacuum (UHV) ring and electrons rotating inside the ring. High voltage is applied to the rotating electrons using variable-frequency radio waves and the frequency is synchronized with the electron rotation during the acceleration of the electrons in the ring. When the electron speed reaches close to the speed of light, a very sharp X-ray beam is emitted in a tangential direction because of the relativistic effect. This X-ray beam is called the SR. Usually SR from a storage ring is used. A ring in which electrons (or positrons) are rotated at a certain constant speed is called the storage ring. Usually electrons accelerated to a sufficient speed by a synchrotron or a linear accelerator are injected into the storage ring, and the tangential radiation when a magnet bends the electron beam is used as an X-ray source. (77) The SR thus produced from a bending magnet is continuous over a wide range (more than 1000 eV) of X-ray energy and a few orders of magnitude stronger than the rotating.
anode X-ray tube. The smaller emittance indicates the electron orbit stored in a storage ring being sharpened, but practically it indicates a smaller X-ray beam size and higher photon density. The emittance is measured in meter · radians (m · rad). The emittance is a measure of beam quality. The smaller the emittance, the more the beam becomes parallel. The SR is monochromated by a single crystal.

Continuous X-rays from a bending magnet are most convenient for X-ray absorption spectroscopic experiments. The rotating axis of monochromator crystals is parallel to the electric vector of the SR X-rays to make good use of the X-rays. To obtain stronger X-rays, SR from an undulator or wiggler beam line is used. The undulator and wiggler are insertion devices in the storage ring, and made of many strong permanent magnets. The electron beam in the storage ring is undulating when it goes through an undulator, and a coherent quasi-monochromatic X-ray beam is produced. It consists of many harmonics and each harmonic has a narrow (say 100 eV) bandwidth. By changing the magnet gap width, the peak energy of the X-rays from the undulator is controlled; the wider the gap, the lower is the energy. Thus, to scan the energy over 1000 eV continuously using an undulator, both the undulator gap and monochromator crystal rotation should be controlled simultaneously. This is a difficult task but now routinely done in some SR undulator beam lines. An undulator can produce a few orders of magnitude stronger X-rays than a bending magnet beam line. If the X-rays produced by undulating by magnets are not coherently interfered, such an insertion device is called a wiggler. X-rays from a wiggler are not strong compared with those from an undulator but are continuous in energy, and thus much easier to use in X-ray absorption experiments than those from an undulator. An example of the experimental set-up of a wiggler is shown in Figure 23.\(^{(78)}\)

SR facilities are classified into first-, second-, and third-generation sources. The first-generation synchrotrons were particle accelerators, and spectroscopists parasitically used the SR. Such SR was unstable. The second-generation synchrotrons use a storage ring to obtain SR but the emittance is still not small enough, i.e. 10\(^{-7}\) mrad. The emittance of the third-generation synchrotrons have emittance as small as 10\(^{-9}\) m · rad. Such a small-emittance storage ring requires a large-radius electron orbit because a large number of magnets are required to keep the electron beam cross-section small. The fourth generation of synchrotron has not yet been constructed and not defined, but may be a free electron laser facility using an electron accelerator. The third-generation SR facilities are tabulated in Table 7, and the second-generation SR facilities can be reached via the links of the Web pages listed.

The first crystal in the monochromator used in an SR beam line experiences a high heat load, and the lattice constant is slightly different from the second crystal. The crystal optics should be cooled by flowing water. To adjust the difference in the lattice constant between the first and the second crystals, usually one of the two crystals is independently finely moved by a piezoelectric

mechanism. The adjustment of the two crystals should always be monitored for the measurement of EXAFS for the 1000-eV range. The monitoring of the adjustment is done by measuring the incident X-ray intensity, which is maximized at every energy point scanned.

6.3 Secondary Yield Techniques and Applications

The intensity of the monochromated X-rays is monitored by an ionization chamber. X-rays pass through the ionization chamber \( I_0 \) and are then incident on a specimen, and the transmitted X-ray intensity is measured by another ionization chamber. The XAS is the plot of \(-\log(I/I_0)\) against the X-ray energy. The absorption spectra are usually measured by this transmission method as shown in Figure 24(a).\(^{79}\) When the X-rays are absorbed strongly by the sample, the secondary responses such as photoelectron intensity, sample electric current intensity, secondary electron intensity (electrons whose kinetic energy < 50 eV is mostly the secondary electrons), Auger electron intensity, and X-ray fluorescence intensity become strong. Therefore, equivalent spectra to the absorption spectra are measurable by these secondary phenomena such as photoelectron intensity, secondary electron intensity, Auger electron intensity (Figure 24b), sample drain current (Figure 24c and d), X-ray fluorescence intensity (Figure 24e), ion intensity due to photostimulated desorption, and other secondary techniques.

The photoelectron intensity for a single crystal has an anisotropy with respect to the observed direction because of the photoelectron diffraction. The angular average of the photoelectron intensity measured as the change in incident X-ray energy is the XAS. This method is called the photoelectron yield method. If Auger electrons are detected, this is the Auger electron yield method. The intensity of Auger electrons from a single crystal also has an angular anisotropy. The detection angle is therefore important for interpreting the observed data for these electron yield methods. Many kinds of electrons are detected, such as secondary electrons, core photoelectrons, valence photoelectrons, and Auger electrons, as shown in Figure 25(a–c).\(^{80}\) The different kinetic energy electrons correspond to the different probing depths. Thus the electron yield spectra are a mixture of various depth spectra as well as a mixture of various processes of electron production. The relation between the X-ray absorption process and the electron emission process is neither direct nor clear.

The electric drain current is of the order of \(10^{-9}\) A when using a bending magnet SR beam line. The electric drain current is a measure of X-ray absorption, and this method is called the TEY method. This is because the drain current represents the sum of all the electrons emitted from the sample. The electrons produced in a solid are scattered in the solid as shown in Figure 26,\(^{81}\) and only electrons produced near the surface contribute to the electric drain current. When we detect ions desorbed from the surface due to X-ray absorption, the ion intensity represents the surface top layer.

These methods of detecting electrons (or electric current) or ions are surface sensitive and therefore are called surface extended X-ray absorption fine structure (SEXAFS). If the sample current is measured in an air or helium atmosphere, then the ejected electrons are converted into \(O_2^+\) or other ions and a positive or negative current is observable depending on the sample electric potential with respect to the ground. This method is called the conversion electron yield (CEY) method.

The XFY method is not surface sensitive, because the fluorescent X-rays originate from as deep a location as the X-ray attenuation length. However, if XFY is combined with the grazing-incidence X-ray technique (Figure 27),\(^{82}\) where the total reflection X-ray technique is combined with the TEY and CEY methods, it becomes more surface sensitive than normal-incidence TEY or
CEY. The X-rays are totally reflected on the surface and the evanescent X-ray wave penetrates only a few nanometers from the surface. X-ray reflectivity is also a measure of XAFS.

The grazing exit angle method is also possible, as shown in Figure 28, because of the reciprocal theorem of optical beams. The XFY method has atomic selectivity because an X-ray detector usually has energy resolution, hence the signal-to-noise ratio is better than in the TEY method, and minor elements adsorbed on the surface can be detected by the XFY method. X-ray absorption spectra of very dilute analytes can be detected using the XFY method; the detection limit is $<10^{12}$ atoms cm$^{-2}$.

The X-rays emitted from a deep location in a specimen suffer from the self-absorption effect and the spectral shape is different from that of an absorption-free spectrum. The XFY method combined with the grazing incidence method does not suffer heavily from the self-absorption effect compared with the normal-incidence method.

Some materials emit luminescence in the visible wavelength range when irradiated with X-rays. This optical luminescence signal intensity corresponds to the

---

**Figure 25** Schematic photoelectron spectra for (a) the excitation energy below the excitation threshold of core level A, (b) just above the absorption threshold but below the photoionization threshold, and (c) far above the threshold. The contributions to the photoelectron intensity from different level photoelectrons and Auger electrons are indicated. At the bottom the window settings for various electron yield X-ray absorption techniques are shown. (Reproduced by permission from Stöhr et al. © 1984 The American Physical Society.)
amount of X-rays absorbed by the specimen. Various processes of optical luminescence de-excitation are shown in Figure 29. Optical luminescence is usually strong for rare earth compounds, but some crystals which have defects in their crystal structure emit stronger luminescence, although a perfect single crystal of the same material does not emit optical luminescence.

The photoacoustic (PA) effect produces sound on irradiating a sample surface by a chopped photon beam. This effect was discovered by Alexander Graham Bell.

Heat is produced while the sample is irradiated by an optical beam and it diffuses during the beam chopping. The chopping frequency usually ranges from a few to a few hundred hertz. The sound wave is detected by a microphone or a piezoelectric device. When the chopping frequency is low, the heat diffuses into deeper location in the sample compared with when it is high. Thus the probing depth is variable by changing the chopping frequency. All the incident photon energy is finally converted into thermal energy through nonradiative transition processes in the solid. The PA process in the visible wavelength range is used for the very sensitive absorption spectrometry of thick bulk samples, which are not transparent to an optical beam. This method has been applied to the measurement of the X-ray absorption, where the incident X-ray beam should be chopped to produce acoustic waves in the sample. This method is a thermal yield method.
Liquid samples are inserted into a cell shown in Figure 30, \(^{87}\) and an electrode is used to measure the photoconductive spectra; electrical conductivity is induced by the incident X-rays. Spectra thus measured are sometimes the inverse of the transmission spectra and sometimes similar to the transmission spectra, depending on the concentration.\(^{89}\) Electrode surface reaction processes can be measured using X-ray absorption in combination with the total reflection X-ray technique.

X-ray submicrometer beams are now available in major SR facilities, and using these beam lines micro- or nanobeam techniques are now applicable, as shown in Figure 31.\(^{89}\) where the XFY is measured by a solid-state detector (SSD). The energy resolution of an SSD is of the order of 100 eV, while the energy shift of an absorption edge is a few electron-volts. If the incident X-ray energy is between the edge energies of two chemical states (say FeO and Fe\(_2\)O\(_3\)), then only one kind of chemical state (FeO) can emit the X-ray fluorescence. Using this technique, chemical state mapping is possible.

Using a bent crystal monochromator as shown in Figure 32, \(^{90}\) multiple-energy X-rays can be focused on a sample and the transmitted X-rays are detected by a position-sensitive detector, which is made of a photodiode array (PDA). Using such a kind of energy-dispersive optics, one spectrum can be measured within a few milliseconds.\(^{91}\) This method is called quick X-ray absorption fine structure (Q-XAFS).

Circularly polarized X-rays can be produced by linearly polarized X-rays transmitted through a diamond single crystal at a special angle depending on its wavelength, which is called the phase retarder, as shown in Figure 33.\(^{92}\) The vertical and horizontal components, the ratio of which is called helicity, of the X-ray electric vector can be controlled by the small rotation and tilting of the diamond crystal. Absorption spectra of a magnetic sample can be measured. This is X-ray magnetic circular dichroism (XMCD) X-ray absorption. The magnetic S and N poles applying the magnetic field to the sample are inverted.

---

or the circularly rotating direction of the X-ray electric field is inverted and the difference in the absorbance is measured. The former is usually used to measure the dichroism. Magnetic thin multilayers have recently become important for information mass storage devices, and these materials are characterized with microbeam XMCD X-rays. The difference in the absorption coefficients for the left and right circularly polarized X-rays is illustrated schematically in Figure 34.\(^{93}\) The details of MCD are described in several books.\(^{94–97}\)

High-resolution X-ray fluorescence spectra of transition metal compounds show multiplet splitting due to the exchange interaction between the unoccupied 3d level and the core X-ray hole. Thus the XFY absorption spectrum of each multiplet line provides spin-selective absorption spectra, as shown in Figure 35.\(^{98}\) This method can measure spin-selective X-ray absorption spectra without applying a magnetic field to the sample. This method is useful for characterizing mixed-valence protein compounds.

The phase transition due to the temperature change is observable, as shown in Figure 36.\(^{99}\) The phase transition is a small change in bond distance and bond angle, and consequently the electronic structure of the sample changes. Thus both XANES and EXAFS region spectra change their line shapes.

The surface of water, where a liquid monolayer is present, could be analyzed by grazing incidence X-ray reflection XAFS.\(^{100}\) When the monolayer absorbs metal

ions from the water solution, the concentration of the metal ion on the surface is slightly higher than that in the water. The coordination structure around the metal ion is analyzed by the EXAFS method.

When a powder is measured by the XFY and TEY methods on a substrate, then the depth-selective chemical state analysis of a fine particle can be performed. Fly ash is a powder of micrometer-sized particles, which are a source of acid rain when they are dispersed in the air. The particles are put on an aluminum foil and irradiated by monochromated X-rays, and XANES spectra are measured by TEY and XFY methods. The TEY method is sensitive to the surface chemical state of the powder particle, and XFY is sensitive to deep parts of the particle (micrometers). The chemical shift of the white line in the absorption spectra is a measure of the oxidation state of an element in the particle.

The surface catalyst process could be elucidated by the analysis of EXAFS spectra. The incident X-ray polarization dependence is an important parameter for the determination of the geometry of a reactant and the surface. X-ray detectors in the XFY method have been developed for X-ray absorption experiments, such as a 19-element Ge detector array; a schematic illustration of a seven-element detector is shown in Figure 23; a 100-element detector array can be used for more efficient detection of X-rays.

Transition metals are usually a target of XAFS analysis, the energy range of which is from 5 to 20 keV. The beamline for X-rays of this energy range uses Be and polymer films as windows to separate the vacuum system from the atmosphere. Both lower and higher energy XAFS experiments require different techniques.

Soft X-ray XAFS experiments, ranging from 0.1 to 5 keV, require UHV techniques. This is because any windows between the SR storage ring and the sample heavily absorb X-rays, hence a windowless beamline is required. Consequently, the sample chamber is made of UHV components and must be baked out up to 200°C. The contaminants in X-ray windows and other X-ray optics are carbon and oxygen, which are in the soft X-ray region (250–600 eV). Hence a windowless system is appropriate for the analysis of these elements. The shortcoming of the soft X-ray region experiment is the UHV system, because samples requiring X-ray absorption analysis could not always be inserted into the UHV system because they would emit gas into the clean system. A vacuum of $10^{-2}$ Pa is sufficient to avoid the absorption of X-rays in the X-ray path. The XAFS spectra of this soft X-ray region are surface sensitive and the profile changes of the spectra due to chemical state are very large. The spectra measured can be used for the same purpose (chemical state analysis) as XPS or ESCA. The detection limit of XAFS is usually lower than that of ESCA, hence XAFS has an advantage over ESCA if SR is available.

XAFS experiments higher than 20 keV require different experimental techniques. The number of application examples is not large, mainly because high-energy X-ray sources are limited without using third-generation SR facilities. In place of measuring this energy range K-edge XAFS, the L-edge XAFS, the energy of which usually falls in the range 5–20 keV, is measured. The L XAFS spectra are composed of L1, L2 and L3 edge jumps, which interfere with each other. To avoid this, the K edge is useful for the analysis. The lifetime of the K hole state of high-energy K-edge XAFS of higher atomic number elements is, however, shorter than the long-wavelength region. Because of the Heisenberg uncertainty principle,
the line widths of the absorption spectral components are as large as 100 eV. Both the EXAFS oscillation and XANES lose fine structure owing to this lifetime broadening. High-energy XAFS has recently been measured with the development of third-generation SR facilities, because the numerical analysis overcomes the short lifetime effect.

7 SOURCES AND DATABASES

Academic societies and E-mail lists discuss the standardization of X-ray absorption spectrometry. As XAFS is used in many areas of research, standardization has been required. To achieve standardization, the International XAFS Society (IXS) was established in the 1990s. The purpose of the IXS is stated as follows:

The International XAFS Society represents all those working on the fine structure associated with inner-shell excitation (near-edge and extended) by various probes (e.g. X-rays and electrons), and related techniques for which the data are interpreted on the same physical basis. The purpose of the IXS is to oversee activities which benefit the community as a whole, to establish operational committees, to provide for education in the field, to disseminate relevant information, to work with other related regional, national and professional organizations in promoting and developing XAS and related disciplines, and to act as representative for the community to other professional organizations.

This society has a close relation to the International Union of Crystallography (IUCr). The WWW home page of the IXS is at Illinois Institute of Technology, http://ixs.iit.edu/, where a large number of XAFS databases are presented. This WWW page links to other related WWW home pages. National society and working groups are active in many countries. All the information concerning these activities is obtainable at the international conferences on XAFS. The first XAFS international conference was held at Daresbury, UK, in 1981, and subsequent conferences are listed in Table 8.

Many kinds of activity reports published by SR facilities are useful sources of experimental methods and standard spectra. Journal sources are listed in Table 9. Fundamental reviews in Analytical Chemistry published in even years relate to X-ray absorption spectrometry. In a book by Meisel et al., references are classified by atomic number and spectral series. Recently several books which treat newer X-ray techniques and concerning X-ray absorption have been published. The Materials Research Society has held symposia on applications of SR in materials science.

The Denver X-ray analysis conference and international conferences on electron spectroscopy, on X-ray and inner-shell processes and on vacuum ultraviolet physics are sources of X-ray absorption spectroscopy and spectrometry.

8 ALTERNATIVE METHODS

8.1 Electron Energy Loss Spectroscopy

An electron beam, with an energy from a few hundred electron-volts to a few hundred kiloelectron-volts, impinges on a sample and loses its kinetic energy. When the sample is a bulk material, reflected electron energy is measured. Usually the loss of transmitted electron energy is measured for thin-film samples less than a few micrometers or a few tens of nanometers thick. This is called EELS. EELS is usually combined with transmission electron microscopy (TEM). The electron energy loss structure is similar to the XAFS. The EXAFS region in EELS is called the extended electron energy loss fine structure (EXELFS). Forward-scattered (0°) electron energy loss spectra, formed when electrons are transmitted in a thin film, are approximately equivalent to the optical spectra; the selection rule is the electric dipole. Energy loss spectra of electrons scattered at a large angle are not treated by the electric dipole transition, and sometimes include optically forbidden transitions. The transmission method used in TEM has a very high spatial

resolution, hence chemical state imaging by the chemical shift of the absorption edge is possible.\textsuperscript{133,134} High energy resolution and high spatial resolution are not always achieved by a single instrument. The EELS spectra are sensitive for low atomic number elements such as boron and carbon. It is not easy to measure the XAFS spectra of these long wavelengths using an SR facility.

8.2 Self-absorption

Although the characteristic X-ray wavelength of an element is usually separated from the absorption edge wavelength of the same element for hard X-rays, they are very close to each other for the soft X-ray region. These close lines are, for example, transition metal L\textsubscript{α,β} X-ray emission lines and L\textsubscript{2,3} absorption edges. The L\textsubscript{α,β} X-ray emission lines emitted in a deep location in a solid are absorbed during the travel in the solid. Hence the X-ray emission spectra have dips due to the X-ray absorption spectra. The profiles of the L\textsubscript{α,β} X-ray emission lines of transition metals excited by different electron energies (3 and 16 keV) change because of the self-absorption effect.\textsuperscript{135} If the electron energy is high (16 keV), then the penetration depth of the electron is deeper. Hence the X-ray emission spectrum suffers heavily from the self-absorption effect. In contrast, if the electron energy is low (3 keV), then the penetration depth is shallow, and the X-ray emission spectrum is free from the self-absorption effect. The comparison of these two spectra yields an X-ray absorption. Similarly, one set of X-ray emission spectra is obtainable by tilting the sample to the X-ray detector or to the incident electron beam, when the electron energy is fixed.

8.3 Extended X-ray Emission Fine Structure

The radiative Auger effect (RAE) is always associated with the X-ray characteristic lines and this effect is an energy loss structure in characteristic X-ray emission, as shown in Figure 37.\textsuperscript{136} The second electron shaken up into an unoccupied orbital has similar information to the XAFS. This is called EXEFS.\textsuperscript{137} This method is used to measure low atomic number elements such as Na, Mg, Al, and Si, because the RAE satellite intensity is strong for these elements. If wavelength-dispersive electron probe microanalysis (EPMA) is available, XAFS spectra of 1 \(\mu\)m diameter area are measurable using this method.

8.4 X-ray Raman Scattering

X-ray Raman scattering is the effect of energy loss on X-ray scattering. Raman scattering is a similar physical process to Compton scattering. The difference is that Raman scattering involves scattering by core electrons whereas Compton scattering involves scattering by conduction band electrons. X-ray Raman scattering is a method for measuring soft X-ray absorption spectra (say of carbon) with a hard X-ray spectrometer (a few kiloelectron-volts). Hard X-rays can be measured in air; soft X-ray absorption spectroscopy, which usually requires UHV, is possible in air by this method. Hard X-rays (8265 eV) impinge on a carbon-containing sample, and the X-rays lose energy by the carbon K edge due to the Raman scattering (ca. 300 eV), as shown in Figure 38.\textsuperscript{138}
The X-ray that should be detected is at ca. 8 keV, which still falls in the hard X-ray region. The XAFS study of catalysts during reaction with gases is possible using the Raman effect.

8.5 Diffraction Anomalous Fine Structure

DAFS was proposed by Stragier et al.\textsuperscript{(139)} XAFS usually measures the wavelength dependence of \( f_2 \), the imaginary part of the atomic structure factor; DAFS measures \( f_1 \). The wavelength dependence of \( f_1 \) and \( f_2 \) has a close relation through the Kramers–Kronig transformation. In the DAFS experiment, the intensity of a diffraction peak of a specimen is measured by the change in the incident X-ray energy. The sample and detector angles (\( \theta \) – 2\( \theta \)) are measured by the change in the incident X-ray energy, or powder X-ray diffraction patterns are measured by the change in incident X-ray energy. This method can measure site-selective XAFS of the same element, because the diffraction peak corresponds to a different site in the crystal. If the diffraction peaks which originate from the surface and bulk phases are separated, space-selective EXAFS-like spectra are obtainable by this method.

8.6 \( \beta \)-Environment Fine Structure

The \( \beta \)-electron emission process in a nuclear conversion process suffers interference by the crystal structure for the same reason as EXAFS. This method is called BEFS.\textsuperscript{(140)}

8.7 Inverse Photoemission Spectroscopy

IPES is an alternative method to measure the unoccupied electronic structure by irradiating electrons and detecting photons.\textsuperscript{(141)} This method is otherwise called bremsstrahlung isochromat spectroscopy (BIS). The extended structure like EXAFS is also observable in BIS and this is called the extended X-ray bremsstrahlung isochromat fine structure (EXBIFS).\textsuperscript{(142)} The BIS is usually combined with an ESCA instrument, and thus occupied and unoccupied electronic structures (similar to XANES) are measurable.\textsuperscript{(143)}

9 CONCLUSION

X-ray absorption spectroscopy is chiefly used in the area of electronic structure study and structural analysis for the study of new materials, surfaces, and catalysts. The spectra measured are surface sensitive or bulk sensitive depending on the detection method. Chemical shift and profile changes are observable. Thus the spectral analysis is useful for materials characterization. This method is also powerful for analyzing mixed chemical states in industrial, environmental, and biological analytes. The development of SR facilities will make it possible to measure nanometer-sized samples in less than a few milliseconds.

1 Introduction

EDXRF is an analytical method for qualitative as well as quantitative determination of elements in a sample, independent of their chemical form. It is built on the fact that elements which are irradiated with energetic X-rays have a certain probability of emitting characteristic X-rays, the energies of which are unique for each element. In the energy-dispersive systems, the emitted X-rays are detected by their energies and not by their wavelengths as in wavelength-dispersive X-ray fluorescence (WDXRF).

EDXRF spectrometers exist at many degrees of sophistication, ranging from advanced laboratory instruments to small portable instruments for field observations. They can be designed for analysis of bulk material or for scanning and elemental mapping of small areas.

Typical applications for EDXRF are analysis of agricultural material, medical samples, archaeological and historical objects and environmental samples such as soil, ores, water and aerosol particles.

1 INTRODUCTION

EDXRF is an analytical method for qualitative as well as quantitative determination of elements in a sample, independent of their chemical form. It is built on the fact that elements which are irradiated with energetic X-rays have a certain probability of emitting characteristic X-rays, the energies of which are unique for each element. In the energy-dispersive systems, the emitted X-rays are detected by their energies. Use of the EDXRF technique has accelerated since the 1960s as a result of the development of solid-state detectors, nuclear electronics and small computers. EDXRF is multielemental and nondestructive and can be applied to large as well as small samples of different composition and character. If conditions are optimized, minimum detection limits (MDLs) can be below the nanogram level for small laboratory instruments and into the femtogram region for more advanced instrumentation [total reflection X-ray fluorescence (TXRF), synchrotron radiation].

EDXRF spectrometers exist at many degrees of sophistication, ranging from advanced laboratory instruments to small portable instruments for field observations. They can be designed for analysis of bulk material or for scanning and elemental mapping of small areas.

2 PHYSICAL PRINCIPLES

2.1 Interactions of X-rays with Matter

When a beam of X-rays impinges on a sample it will react with the atoms in the sample by three processes, namely the photoelectric effect and coherent (Rayleigh) and incoherent (Compton) scattering. For the photoelectric effect to occur, the energy of the impinging photons has to be large enough to create a vacancy in one of the shells of the studied elements. The photoelectric effect may result in emission of characteristic X-rays, but once a vacancy has been created in an inner shell the atom can also get rid of the excitation energy by emission of an Auger electron. The probability that characteristic X-rays will be emitted – and not an Auger electron – varies from one element to another and is described as the fluorescence yield. For elements of low atomic number, emission of Auger electrons dominates, whereas emission of characteristic X-rays is more likely for elements of high atomic number. A sketch of the X-ray fluorescence (XRF) process leading to emission of a characteristic X-ray is shown in Figure 1.

The scattering processes are of two types, incoherent and coherent. The probabilities of both kinds of scattering vary with photon energy and the composition of the sample. The scattered X-rays are an important part of the background radiation on which the characteristic peaks are superimposed. Figure 2 shows a typical X-ray spectrum with characteristic and scattered radiation.

![Figure 1](image1.png)

**Figure 1** Schematic drawing of the XRF process in an atom: An incident photon of energy $E_0$ transfers its energy to an electron in the K-shell. The electron is expelled from the atom and leaves a vacancy. An electron from the L-shell makes a transition to the K-shell to fill the vacant site. The difference in binding energy between the two shells, $E_K - E_L$, is used by the atom to emit a characteristic X-ray of energy $E_i$. Note that the distances between the atomic shells are not drawn to scale.

![Figure 2](image2.png)

**Figure 2** X-ray spectrum of a National Bureau of Standards (NBS) standard biological sample, 1571, “orchard leaves”, measured in a secondary target EDXRF spectrometer of the geometry of Figure 3. The sample thickness is 30 mg cm$^{-2}$. The excitation conditions were as follows: tube voltage 55 kV, current 10 mA. The characteristic Kα lines are denoted by chemical symbols, except for Pb, for which both Lα and Lβ are marked. Note the high intensities of the coherently and incoherently scattered Kα and β radiation of the secondary target, which in this spectrum is Mo. The X-ray spectrum has been recorded with a Si(Li) detector.
2.2 Principles in Quantitative Evaluation of Element Concentration

The quantitative evaluation of element concentrations in EDXRF depends on whether the source is monochromatic or contains a range of different energies. Polychromatic X-ray sources can, however, be treated as a sum (or an integral) of monochromatic sources, and the discussion below is therefore limited to the case of monochromatic excitation. For this case, and with further limitations to homogeneous samples and in the absence of interelement effects, a simple relationship can be obtained between the mass thickness (or areal density), \( m_i \), of a specific element and the measured intensity \( I_i \) of its characteristic X-ray peak:

\[ I_i = I_0 K_i m_i D_i \]  

(1)

In Equation (1) the following notation is used:

- \( I_0 \) = the intensity of the primary beam of energy \( E_0 \), which, in the case that the source is a secondary-target X-ray tube arrangement, is influenced by anode material and operating voltage and current.
- \( I_i \) = the intensity of characteristic X-rays (K- or L-radiation) of element “\( i \)” of energy \( E_i \).
- \( D_i \) = a correction factor for attenuation of both the incident X-rays and the characteristic X-rays of element “\( i \)” in the sample.
- \( K_i \) = a factor that depends on the set-up of the instrument and basic physical processes.

The amount of analyte is often written as:

\[ m_i = W_i m \]  

(2)

In Equation (2) \( W_i \) is the weight fraction and \( m_i \) is the mass thickness of element “\( i \)” in the sample.

\( K_i \), thus depends on instrumental factors and on fundamental physical parameters related to the energies of the incident and characteristic X-rays. Important parameters to consider are:

- the geometry of the XRF spectrometer;
- the attenuation of the exciting and characteristic radiation along the beam paths and in the detector window;
- the detector efficiency for radiation of energy \( E_i \);
- the probability of producing a vacancy with incident radiation of energy \( E_0 \) in the relevant shell of element “\( i \)”;
- the fluorescence yield of element “\( i \)”.

Note, however, that the essential feature of Equation (1) is that – under the assumptions of homogeneity and absence of interelement effects in the sample – the factor \( K_i \) is independent of the mass thickness, \( m_i \), of the analyzed element and of the attenuation correction, \( D_i \). Thus, it can be determined through calibration of the instrument if it is operated under well-defined conditions.

The attenuation correction, \( D_i \), in Equation (1) has the form given in Equation (3):

\[ D_i = \frac{1 - \exp\left[-\frac{(\mu(E_0) \csc \Phi_1 + \mu(E_i) \csc \Phi_2)m}{\mu(E_0) \csc \Phi_1 + \mu(E_i) \csc \Phi_2} \right]}{\mu(E_0) \csc \Phi_1 + \mu(E_i) \csc \Phi_2} \]  

(3)

In this expression \( \mu(E_0) \) and \( \mu(E_i) \) are the mass attenuation coefficients for the exciting and characteristic radiation of energies \( E_0 \) and \( E_i \) respectively. These can be expressed as weighted sums of the individual mass attenuation coefficients for all elements in the sample. \( \Phi_1 \) is the glancing angle between the exciting radiation and the sample plane and \( \Phi_2 \) the glancing angle between the characteristic radiation and the sample plane. There are two cases for which the attenuation correction and thus Equation (1) takes on an especially simple form, namely for “thin” and “infinitely thick” samples (see Appendix 1).

In some cases it is also necessary to take into account the fact that the characteristic radiation produced in one element as well as the scattered radiation can cause fluorescence in another element (interelement and related effects, as discussed below). This may lead to enhancement of one spectral line and further attenuation of another. Furthermore, to perform quantitative evaluation one needs to know whether impurities are present in the spectrometer material and the properties of the detector.\(^{(1–3)}\)

From Equations (1) and (2) it is evident that the net areas of the characteristic peaks in the X-ray spectrum will have to be evaluated in order to determine element concentrations in a sample. This can be done automatically by means of computer programs. In evaluation of net peak areas in a spectrum, the problem of interference between spectral lines will, however, have to be addressed. In a number of cases, the K-lines from one element will overlap or coincide with the L-lines of another element, as is illustrated in Figure 2 by the overlap of As K\( \alpha \) with Pb L\( \alpha \). In other cases, the K\( \alpha \) from one element will coincide with the K\( \beta \) from another. By knowing relative ratios, K\( \alpha \)/K\( \beta \), L\( \alpha \)/L\( \beta \), it is possible to resolve the overlapping peaks. However, this procedure will reduce the accuracy of the measurement to an extent determined by the statistics of the measurement.

2.3 Interelement Effects

In a matrix composed of many elements, each element will interact with the radiation from all other elements. If the matrix elements have characteristic radiation that is on the short wavelength side of the absorption edge
of the element of interest, element \(i\), conditions may be favourable for enhancement of the lines of element \(i\). The combined effects of the matrix elements on each other are often called interelement or absorption-enhancement effects. Enhancement effects are especially important for cases in which the analyte is present at trace level and the enhancing elements at percentage levels. In order to illustrate this, consider the determination of one element, \(i\), by measuring its \(K\alpha\) radiation in a matrix consisting of lighter as well as heavier elements. In this case, the lighter elements will not be able to enhance the characteristic \(K\alpha\) radiation of the element \(i\) because their characteristic radiation will not be energetic enough to create the necessary vacancy in the \(K\)-shell of element \(i\) (see Figure 1). Thus, it is necessary to look at the effects of the heavy elements in the sample. If their \(K\alpha\) energies are lower than that of the absorption edge for the \(K\)-shell in element \(i\) they will not cause enhancement. If, on the other hand, their \(K\alpha\) lines have higher energies than that of the \(K\)-shell absorption edge they will enhance the \(K\alpha\) radiation of element \(i\) – in fact they are well matched for doing so. However, the general problem of determining whether or not enhancement will occur is not so difficult for homogeneous samples, since absorption edge energies for different shells and characteristic X-rays for all elements are long known and readily available in tabulated form in textbooks.

A situation similar to the interelement effect occurs when the backscattered exciting and/or fluorescent radiation excites the elements in a thick sample. These effects are of relatively large importance for analysis of trace elements embedded in organic matrices, since the medium-weight and heavy elements are usually present in low concentrations and the incoherent scattering in these cases is dominating. \(^{41}\) (Compare the spectrum from the organic specimen as given in Figure 2.)

### 2.4 Dependence of Detection Limits and Penetration Depth on X-ray Energy and Source Characteristics

The intensity of a beam of X-rays passing through a sample is attenuated by the above-mentioned photoelectric and scattering processes according to the exponential law:

\[
I(E) = I_0(E) \exp\left[-\mu(E)p x\right] \tag{4}
\]

In Equation (4) the following notation is used:

\[
I_0(E) = \text{the original intensity of the beam.}
\]

\[
I(E) = \text{the intensity after the beam has travelled a distance } x \text{ in the sample.}
\]

\[
p = \text{the density of the sample.}
\]

\[
\mu(E) = \text{the mass attenuation coefficient of the sample material.}
\]

Since the three attenuation processes that contribute to the total attenuation of the beam are independent of each other, the mass attenuation coefficient can be written as a sum of coherent, incoherent and photoelectric mass attenuation coefficients. Each process has a functional dependence of the photon energy, \(E\), and this is shown explicitly in Equation (4).

#### 2.4.1 Penetration Depth

A relevant question in XRF analysis is how deeply the X-rays will penetrate into the material. A quantitative measure of this can be given in terms of the penetration depth, which is usually defined as the path length needed for the intensity of the X-rays to be reduced by a given factor. Since the mass attenuation coefficients, \(\mu(E)\), in Equation (4) vary widely with X-ray energy and material composition, penetration depths are indeed very different for hard and soft X-rays and vary appreciably with sample composition. Table 1 shows some typical values for penetration depths for characteristic X-rays of some elements embedded in an iron and in a carbon matrix. \(^{5}\) In this example, the penetration depth varies by 3–4 orders of magnitude. Generally, X-rays of low energy do not penetrate very far in a matrix of heavy material, whereas high-energy X-rays in a light material have high penetration. This fact has a large influence on whether corrections for attenuation have to be made when quantifying element concentrations. Concepts such as “thin” or “thick” samples are always seen in relation to the energy of the X-rays of interest.

#### 2.4.2 Minimum Detection Limit

A widely used definition for the MDL in EDXRF is the concentration (or, alternatively, the amount of mass)

needed for the number of counts in the characteristic peak of an element to be equal to or larger than $3\sqrt{B}$, where $B$ is the number of counts in the background below the peak of element $i$ [5,6] ($\sqrt{B}$ corresponds approximately to one standard deviation). Specifically:

$$\text{MDL} = \frac{3\sqrt{B}}{k_i} \quad (5)$$

where $k_i$ is the corresponding sensitivity constant measured as the net number of counts in the characteristic peak per unit concentration.

Since the attenuation of X-rays is stronger for soft X-rays than for hard X-rays, and the background in many designs of EDXRF spectrometers is rather flat for energies below the scattered radiation, optimum values for MDL are usually obtained for medium-weight elements. From Equation (5) it can be seen that the general problem in lowering detection limits can be achieved by finding ways of increasing the intensity of the characteristic peak while decreasing the intensity of the background radiation. A substantial portion of the background radiation is due to incoherent and coherent scattering of the primary radiation in the sample itself. These scattered peaks will, by means of secondary processes in the sample, give rise to a general increase in the background also at lower energies. Furthermore, the scattered radiation will also contribute to an increase in the background level owing to incomplete charge collection and other processes in the solid-state detectors. Therefore, sample properties that influence scattering processes, for example thickness and average atomic number, have an essential influence on the detection limits in an EDXRF spectrometer.

The counts in both peak and background are time dependent, but in different ways: the peak increases linearly with time, whereas $\sqrt{B}$ increases with the square root of time. This means that the detection limit will be reduced as analysis time is increased, and the analyst can use this fact if elements present in low concentrations are of special interest. The price for improvement in MDL is, of course, a longer running time for the spectrometer. For many laboratory instruments, collection times in the range 200–1000 s for each X-ray spectrum are chosen.

In practice, for bulk samples of organic material, MDLs are of the order of 0.1 ppm for laboratory instruments for monochromatic sources with energy matching the binding energy for the K-shell of the element of interest. In bulk geological samples, MDLs are generally somewhat larger. Measured as absolute amounts (for example in mass units), the lowest MDLs can reach the picogram region for thin samples (especially with TXRF) and the femtogram region for micro beams that utilize a focused synchrotron beam as source. MDLs in the $10^{-10}$ g region are reached for many elements in thin and thick samples in laboratory EDXRF spectrometers.

2.4.3 Sensitivity

A concept that is often used to describe the performance of an EDXRF method is the sensitivity, which is defined as the change in instrument response (net number of counts in a characteristic peak) per unit change in the concentration of a measured element. Thus, sensitivity in X-ray instruments can be given as count rate per ppm. The sensitivity concept is useful for comparing analyses of different elements in a given spectrometer. It varies to a high degree with the difference in energy between the incident and the characteristic radiation and is highest if the energy of the incident radiation is only slightly greater than the energy of the K-edge for the element in question.

However, sensitivity in XRF instruments is expressed as count rate per ppm) is a measure of the excitation capability for each element with a specific XRF instrument. Usually, sensitivity is not used for comparing different instruments. For reasons of comparison, a more appropriate parameter is the MDL achieved with each instrument.

3 ENERGY-DISPERSIVE X-RAY FLUORESCENCE INSTRUMENTATION

3.1 General Features

A typical feature in element analysis in practice is that samples may contain major as well as trace concentrations of different elements. Samples such as alloys, mineral ores and ceramics usually contain a number of elements, the concentrations of which may vary by several orders of magnitude.

In an energy-dispersive X-ray spectrometer, the important parts to consider are the X-ray source, the beam and spectrometer geometry and the detector. An obvious goal for the designer of XRF spectrometers is to maximize the intensity of the characteristic X-rays from the elements while keeping the background radiation as low as possible. Most energy-dispersive (ED) spectrometers have an elemental range from Na to U and, if special detectors with ultra-thin windows are used, the range can be extended to still lighter elements such as C. There are many different designs of ED spectrometers for laboratory and field work. Combinations of WDXRF and EDXRF systems are also used, in which the better resolution of wavelength-dispersive (WD) instruments is utilized for the lightest elements and the simplicity and higher sensitivity of ED systems is utilized for elements above Ca. The cost of an ED system is about US$ 20 000 and upwards.
3.2 X-ray Sources

In photon-induced XRF, the most common sources are X-ray tubes, which can be used directly for broadband excitation or in combination with filters or secondary fluorescers to obtain semimonochromatic radiation. In some spectrometers, especially portable instruments for field work, and for problems in which only one or a few elements are of interest (for example in routine process control), radioisotopes are useful.

3.2.1 X-ray Tubes

In X-ray tubes, the radiation spectrum is influenced by two major processes that occur when electrons are accelerated by the high voltage from the cathode to the anode. One process is the creation of characteristic X-rays in the anode material itself, which occurs when the kinetic energy of the impinging electron is larger than the binding energy of a particular shell in the anode material. The other process is the creation of continuous bremsstrahlung, which is created when the electrons are slowed down in the anode. The bremsstrahlung spectrum contains energies from zero up to the kinetic energy of the electrons, which is equal to the electron charge times the tube voltage. Accordingly, the spectrum from the X-ray tube contains a continuous distribution overlaid with the characteristic radiation from the anode material. By varying parameters such as anode material and thickness, tube voltage and current settings, the broadband spectrum from the X-ray tube can be optimized for the elements of interest. Some X-ray tubes are equipped with dual or multiple anodes.

As the MDL for a given element is dependent on the intensity of the characteristic as well as the background radiation (Equation 5), there is often a desire to use monochromatic or semimonochromatic radiation. This can be achieved by use of filters and/or secondary target arrangements. Filters inserted between the X-ray tube and the sample will allow transmission of the characteristic line of the filter but will attenuate the low-energy part of the tube radiation by a substantial factor. Thus, filtering may change the shape of the tube spectrum and improve MDLs for elements lighter than the filter material. By varying filter material and filter thickness, this method can give a high flexibility in the use of tube excitation.

In secondary-target arrangements, the radiation from the X-ray tube is allowed to excite a target of a material whose characteristic radiation (almost monochromatic) is used as a source to excite the sample. Figure 3 shows an arrangement of this kind. The material in the secondary target can be chosen so that its characteristic radiation is just above the K-edge of the elements of most interest in the sample. The anode material in the X-ray tube is generally chosen to have a high output over a wide range of energies in order to allow different secondary target materials to be used. Although the intensity of the primary beam is reduced considerably by the secondary target arrangement, the technique usually gives low detection limits for many elements. This is mainly because of the low background in the X-ray spectra (see Figure 2). Other techniques to modify the output from an X-ray tube utilize scatterers to polarize the X-rays or multilayers, as demonstrated for TXRF spectrometers.

For microbeam EDXRF, microfocus low-power X-ray tubes with anode spots of the order of 100 µm² are now available, as are high-intensity rotating anode sources (18 kW) with various focal spot sizes.

3.2.2 Radioactive Sources

Radioisotopes as X-ray sources utilize the γ-rays from the decay of the radioisotope or the characteristic X-rays emitted from the decay product. The output intensity is lower than that which can be achieved by an X-ray tube, but the advantages are that the intensity of the source is stable and no electric power supply is needed. Radioisotopes are therefore practicable in portable field instruments. The drawback is the limited half-lives for some of the most used isotopes (for example 2.7 years for ⁵⁵Fe with 5.9- and 6.4-keV X-rays and 1.3 years for ¹⁰⁹Cd with 22.2- and 25.5-keV X-rays plus 88.2 keV γ-rays). The most common geometry of the radioisotope sources is either that of a point source or that of an annular source. The sensitivity and MDLs are for some instruments
almost identical to those for X-ray tube secondary-target arrangements.\(^{(12)}\)

### 3.2.3 Synchrotron Radiation

Synchrotron radiation is ideal as a source for EDXRF, since it can be obtained at the desired energy with high brilliance. Furthermore, it is polarized, which is useful for decreasing scattered radiation and thus reducing the background. Synchrotron radiation at the National Synchrotron Light Source (NSLS, Brookhaven National Laboratory) with collimated and focused X-rays of high energy has been used in an X-ray microscope mapping trace elements with a spatial resolution of \(10 \times 10\mu\text{m}^2\) and with MDLs into the femtogram region for thin specimens.\(^{(7)}\) However, synchrotron radiation is expensive and is not generally available in research laboratories.

### 3.3 Energy-dispersive X-ray Fluorescence-spectrometer Designs

As pointed out before, there are three main points to consider for achieving good performance in an EDXRF system, namely the X-ray source, the detector and the design of the spectrometer. A few things of importance for the design will be mentioned here, namely beam geometry, choice of materials and compactness of the design.

The problems will be discussed from the perspective of a secondary-target set-up but are easy to generalize to other arrangements.

#### 3.3.1 Beam Geometry

A large part of the background signals in X-ray spectra depends on primary and secondary scattered radiation in the sample. This can be illustrated in the secondary target XRF arrangement shown in Figure 3. In such a system, contributions to the background in the final spectrum are obtained from: (a) the primary radiation from the tube, (b) the semimonochromatic beam from the secondary target and (c) the radiation from the sample.

The primary radiation from the X-ray tube is very intense and, although it will be scattered twice (in the secondary target and the sample), it is likely to contribute to the background unless special care is taken. The radiation from the secondary target will be scattered when reaching the sample and constitutes the two large scattered peaks shown in Figure 2. These peaks have been observed to be responsible for part of the flat background in the low-energy region by multiple scattering in the sample and by incomplete charge collection effects in the detector.

From basic physical principles it is well known that scattering is at a minimum when the scattering angle is 90°. Thus, it is important that the impinging and emitted radiation form an angle of 90° with respect to each other. This will be achieved if the secondary target and the sample are both oriented with angles of incidence of 45° with respect to the beam directions. Because the radiation from the X-ray tube is scattered twice – in the secondary target and in the sample – and since the reason for scattering at 90° is to utilize both minimum scattering cross-section and the production of a polarized beam, it is also of importance that the geometry of the three beam paths is a three-axial (\(xyz\)) geometry as shown in Figure 3 and not a \(xyz\) planar geometry.\(^{(13)}\)

#### 3.3.2 Choice of Materials – Compact Designs

In an EDXRF spectrometer the major part of the primary radiation emitted by the tube and secondary target will not be directed towards the sample but will interact with the material in the spectrometer. This interaction will take place by means of the same processes as occur in the sample itself. Different materials have different abilities to scatter and absorb radiation, and the purity of the material will have an influence on whether characteristic lines from impurities in the material close to the beam paths will pass into the detector. Thus, it is important that the materials in objects such as filters and collimators are of the highest possible purity.

Another important aspect to consider in an XRF set-up is the actual geometric dimensions of the various parts of the spectrometer. Since the general goal is to have efficient and high sensitivity in the instrument, long beam paths are of disadvantage. In air, a long beam path for the radiation from sample to detector will contribute to the attenuation of characteristic radiation from the sample, and thus significantly reduce detection efficiency for light elements in particular. Thus, a geometry as compact as possible with short beam paths is desirable. However, the material in the housing of the spectrometer has to be chosen so that unwanted radiation can be stopped efficiently. The combination of compact geometry and high stopping efficiency generally means that light materials such as aluminum should be avoided.

Another aspect to consider in relation to Figure 3 is the position of the sample. In many spectrometers, the sample position is vertical, which means that samples have to be self-supporting. By choosing an arrangement in which the sample plane is horizontal and the detector looks down at the sample, a more versatile instrument is achieved, in which the sample can also be in non-self-supporting forms, for example as liquids and powders. With a vertical sample position, such specimens are difficult to irradiate directly by the beam.
3.4 Detector Characteristics

For ED spectrometers, liquid-nitrogen-cooled Si(Li) detectors are the most widely used, having their optimum performance for X-rays of an energy ranging from a few to about 25 keV. For K-lines from heavier elements (30–140 keV) Ge(Li) and high-purity germanium detectors are preferable owing to better detection efficiency in this region. For benchtop and portable spectrometers, scintillation counters and gas-filled proportional counters are sometimes used, often in combination with filters to compensate for the lack of energy resolution. Other types of detectors have been developed, for example mercury iodide detectors at room temperature for high- and medium-Z-element analysis. High-purity silicon detectors are now able to separate K fluorescence lines down into the 1 keV region and compare well with compound semiconductor detectors such as CdZnTe and HgI₂.

4 SAMPLE HANDLING AND QUANTIFICATION IN PRACTICE

4.1 Sample Preparation

A typical feature in element analysis in practice is that samples may contain high as well as trace concentrations of different elements. Samples such as alloys, mineral ores and ceramics usually contain a number of elements whose concentrations may vary by several orders of magnitude. EDXRF analysis can be performed on a vast number of samples of very different composition and status. Examples of common samples are:

- geological – for example minerals, rock, soil and sediments;
- biological – roots, leaves, stems, moss, lichens, algae, fish, animals;
- medical – blood, hair, skin, muscle, brain, teeth, bone, enzymes;
- industrial – metals, ores, paper, pulp;
- cultural – pottery, paintings, statues, coins, books, clothes;
- environmental – water, air pollutants, waste, pollen.

There is no strict division between the different categories, but the above list gives an idea of the diversity of the samples concerning range of elemental concentrations – from traces in biological material to major components in minerals – as well as the range of densities involved. The material may exist in different forms, such as airborne particles, liquids and solids.

4.1.1 Solid Samples

Homogeneous samples for which the concentrations of the elements of interest are significantly larger than the detection limits (usually 0.1–1 ppm) are conveniently analyzed without any sample preparation. This is a great advantage, since a minimum of sample treatment will minimize the risk of contamination. Many samples belong to this category.

Some samples may have sufficiently high element concentrations but be inhomogeneous and contain grains of different sizes. In view of the poor penetration depths for X-rays from light elements, the grain size may affect the quantitative evaluation. For such samples either grinding into a fine powder or digestion and dilution may be necessary.

4.1.2 Liquid Samples

Trace elements in water samples can be present in different forms, for example as insoluble particulates or as colloidal or as soluble species. Suspended material can be separated by filtration, and the deposits on the filter can be directly analyzed in the X-ray spectrometer. For water, many element concentrations are below MDLs, especially for heavy metals. The colloidal and soluble fractions may therefore need preconcentration, which may be achieved by evaporation due to heating or by freeze-drying. Care must be taken, however, to avoid loss of volatile elements in these processes. A freeze-dried residue may be acid digested. A number of other chemical preconcentration procedures have been used on natural waters, snow and rain, with acceptable precision and recovery rates. Many of these techniques have the advantage that they increase element concentrations while at the same time giving rise to thin film samples that are easy to evaluate quantitatively. For many fluids – and in particular if TXRF technique can be used – the fluid can be deposited directly onto a carrier and dried at low temperature.

4.2 Quantitative Analysis of Major or/and Trace Constituents

As seen from section 3.2, quantification involves knowledge of some factors that are different for each spectrometer (geometrical properties, detector and source characteristics, etc.) and some parameters that are dependent on physical processes. In a practical case, both these aspects have to be taken into account.

4.2.1 Homogeneous Samples: General Approach

Samples analyzed in spectrometers with monochromatic or nearly monochromatic X-ray sources are usually rather
easy to work with, since Equations (1–3) and (6–8)
can be used for quantitative evaluation. A convenient
approach is to calibrate the spectrometer with known
standards, which are either thin or of known mass
thickness. Calibration gives information on the factors \( K_i \)
for different characteristic X-ray energies. These factors
can be stored for a special configuration of a given
spectrometer and used for element quantification of the
unknown samples. If an unknown sample is considered to
be thin for some elements \( \left(D_i = 1\right) \), the amounts of these
elements can be readily evaluated by use of Equation (6).
If the sample is of intermediate or infinite thickness,
the attenuation factors \( D_i \) will have to be evaluated
either from measurements of mass thickness or from
information contained in the coherently and incoherently
scattered radiation, as discussed below.

For polychromatic X-ray sources, for example broad-
band excitation from X-ray tubes, Equation (1) is not
valid. In this case, the intensity, \( I_i \), can be described by
an integral over the distribution of excitation energies.
In practice, the approach often used is to calibrate the
instrument with standards as similar as possible to the
investigated samples.

A special case of homogeneous samples is liquids.
For most liquid samples, quantification is facilitated by
the ability to spike the sample with internal standards
before digestion or further treatment. By choosing two
internal standards with different attenuation properties,
the attenuation for all elements in the sample can be
obtained together with information on the sample mass
thickness.

### 4.2.2 Heterogeneous Samples

For heterogeneous samples, quantitative evaluation is
more difficult, and this is particularly the case for X-rays
from light elements, for which the penetration depths
of the characteristic X-rays are small. Another problem
with heterogeneous samples is the profile of the X-ray
beam itself. In the ideal case, the beam intensity should
be constant over the beam area and drop abruptly to
zero at the edges of the beam. In reality, the beam
intensity does not behave so well, at least not for the
radiation from X-ray tubes. Owing to the geometrical
effects and different path lengths for different parts of
the radiation from the tube to the sample, the beam
may not have a homogeneous intensity distribution.
This has also been shown to be the case for secondary-
target arrangements.\(^\text{18}\) Thus, for laboratory instruments,
knowledge of intensity variations within the beam is
essential for heterogeneous samples. Alternatively, one
can achieve good accuracy for heterogeneous samples
and beams by scanning the sample, so that effects due to
sample and beam inhomogeneity can be leveled out.

### 4.2.3 Methods for Quantification in Practice

Many samples can be regarded as “thin” for medium
weight and heavy elements, but in reality few samples are
thin with respect to light elements (see Table 1). Thus,
one will often have to evaluate the attenuation properties
of the sample, at least for some elements. Many methods
have been developed to assist quantification. Some of
these use an experimental approach, whereas others
build on the fundamental parameters of the physical
processes involved, often in combination with knowledge
after calibration of the instrumental performance. A
few methods to illustrate the principles in quantitative
evaluations for nonliquid samples will be described.

The first method, which was one of the earliest, is
the emission–transmission method.\(^\text{1,2}\) A precondition is
that the sample is of “intermediate thickness”, as defined
in Appendix 1. The method is based on an independ-
ent measurement of the factor \( \exp \left[ \left( \mu(E_i) \csc \Phi_i + \mu(E_o) \csc \Phi_o \right) m \right] \),
which is contained in the attenuation correction, \( D_i \).
This factor, which measures the sample
attenuation, can be directly evaluated by three
measurements:

1. First the characteristic radiation from an element “\( i \)” in
   the sample is measured.
2. Under identical conditions, the same characteristic
   radiation is measured from the combination of the
   sample and a target of element “\( i \)” positioned behind
   the sample.
3. In the third measurement, the characteristic radiation
   is measured from the target of element “\( i \)” alone,
   without sample.

It is not difficult to show that these measurements
will give knowledge of the factor \( \exp \left[ \left( \mu(E_o) \csc \Phi_o + \mu(E_i) \csc \Phi_i \right) m \right] \),
which is needed in Equation (3). If this
factor is known, it is straightforward to calculate
\( m_i \) of element “\( i \)” from measurement of \( I \),
and knowledge of the instrumental factors \( K_i \)
and \( I_0 \) according to Equation (1).

Another well-known method is to make use of the
information contained in the coherent and incoherent
scattering of the incident (exciting) radiation. Under
certain conditions, the intensity of the scattering peaks
or combinations of these can be used as internal
standards.\(^\text{1,2,19–21}\) From Figure 2, which is an X-ray
spectrum from a biological sample, in which molybdenum
has been used as secondary target, it is seen that the
incoherently scattered radiation is very pronounced. In
a biological or other kind of light element sample in
which medium and heavy elements are present at trace
levels, the incoherently scattered radiation is essentially
a measure of the mass seen by the impinging beam. The
argument for this is that for the light elements (except
hydrogen) e.g. carbon, nitrogen and oxygen, which are
the main constituents in most biological samples, the mass of an atom is closely proportional to its atomic number (Z).

Furthermore, the binding energies of the electrons in the light elements are small compared with the energy of the exciting radiation. Thus, the exciting radiation essentially sees a cloud of free electrons, and the probability of incoherent (Compton) scattering will be proportional to the number of electrons, which in turn is approximately proportional to the sample mass. This approach is also valid for some elements of importance in geochemical samples, such as Mg, Si and Ca (ratios of relative atomic mass to atomic number: 2.03, 2.01, 2.00) but less so for Na, Al and K (ratios of relative atomic mass to atomic number are in the range 2.09–2.06). For samples composed of heavy elements, the ratios of atomic mass to atomic number will be changed owing to increased neutron excess in the atomic nuclei. Furthermore, the binding energy of the inner electrons increases and the free electron incoherent scattering cross-section is no longer such a good approximation. Secondary scattering effects in the material may also appear. Several practical methods, however, have been developed in which use is made of the information contained in both coherently and incoherently scattered radiation for thick samples of geochemical origin. Giauque et al. and Giauque have used the ratios of the incoherently scattered radiation from Ag Kα and Kβ radiation together with the coherently scattered Ag Kα to ascertain sample mass thickness and photoelectric cross-sections for thick geochemical samples. Also, in the case of WDXRF, the scattered Compton lines from the X-ray tube have proved to be useful as internal standards in light element samples.

The general aim of quantification in EDXRF is to arrive at the sample composition from the information contained in the spectrum. In an XRF spectrum the medium-heavy and heavy elements in the sample will reveal their presence by their characteristic radiation as well as by their contribution to the coherently and incoherently scattered radiation. Thus, a first estimate of the relative abundance of these elements can be made directly from the spectrum. As discussed earlier, however, this first estimate will be significantly modified by considering attenuation and interelement effects, etc. To evaluate the mass thickness of the light elements—which do not show up by their characteristic X-rays—their contribution to the scattering peaks can be determined from the spectrum by subtraction of the scattering due to the medium-heavy and heavy elements. From this evaluation, the total mass thickness from light as well as medium and heavy elements can be calculated.

In an iterative process, in which all the information from the elements through their characteristic as well as scattered X-rays is used, the concentrations can be recalculated until the concentration values obtained agree with the experimental spectrum.

In the practical situation, the analyst is dependent on computer programs in which an X-ray library is stored together with information on the actual spectrometer (obtained by calibration samples). Spectrum evaluation programs are available in commercial instruments and from research groups. A more or less continuous development of these programs takes place, in which peak shapes and background profiles are described by model functions.

4.3 Surface Analysis and Microanalysis
Quantification of thin surface layers or microstructures essentially makes use of the same fundamental methods as discussed above, namely adding of an internal standard for liquids, use of external reference material and use of scattered radiation. For thin self-supporting homogeneous solid surface layers, quantification can be achieved by use of scattered radiation, calibration constants (Equation 6 in Appendix 1) or fundamental parameters.

In the case of heterogeneous microstructures smaller than the X-ray beam diameter, quantification by means of external references is difficult in spectrometers based on X-ray tubes owing to the inhomogeneous beam profile as discussed above and the difficulty in positioning the samples within the beam. In these cases internal standards such as the scattering peaks from the sample will give reasonably good average values, although structures with resolution below 10 µm are presently difficult to study with laboratory equipment.

5 CONCLUSIONS: NEEDS FOR FUTURE DEVELOPMENTS
Although EDXRF has many advantages, in that it is multielemental, nondestructive and needs a minimum amount of sample treatment, it has two distinct disadvantages:

- For bulk samples it is not very sensitive. MDLs for laboratory equipment are in the order of 0.1 ppm. Measured in mass units, it has MDLs of the order of a fraction of a nanogram for the best cases in realistic samples. For synchrotron radiation sources and special designs [TXRF, grazing emission X-ray fluorescence (GEXRF)] MDLs may be reduced by several orders of magnitude, but not for all kinds of samples. A substantial part of the lack of sensitivity
for bulk samples is due to effects caused by the presence of the large scattered peaks entering the solid state detectors.

- In comparison with microprobes with charged particles – electrons or protons – microprobes of X-rays with high lateral resolution are difficult to obtain. This is because charged particles can be steered by electric and magnetic fields, whereas X-rays will have to be focused with mirrors or other kinds of optical devices. The advantage of X-rays over charged particles is that they deposit less energy into the sample and thus will cause less heating and loss of volatile material.

Future development which would imply breakthrough on the above items would be:

- improvements in detector technology to minimize effects that cause increased background, for instance trapping and polarization in the detector material;
- development of laboratory X-ray lasers in order to obtain parallel, polarized and intense beams.

For both these developments it is easy to observe that not only EDXRF but a vast field of other analytical methods would benefit from them.

APPENDIX 1 APPROXIMATIONS FOR “THIN” AND “INFINITELY THICK” SAMPLE THICKNESS

The sample thickness for an element can be divided into three categories as follows:

- “Thin” sample: the intensity of the characteristic X-rays from a certain element increases linearly with the amount of analyte in the absence of interelement effects.
- “Infinitely thick” sample: an increase in sample thickness does not give rise to any increase in the intensity of the characteristic X-rays.
- Samples of “intermediate thickness”: the intensity of the characteristic X-rays grows with sample thickness but it does not grow linearly.

Using the same notation as used in Equations (1–3), these equations take on simple expressions. Thus, for “thin” samples, in which \( m \rightarrow 0 \), \( D_i = 1 \) and, as shown in Equation (6)

\[
I_i = I_0K_im_i = I_0K_iW_im
\]

For “infinitely thick” samples (\( m \rightarrow \infty \)), Equations (7 and 8) apply,

\[
D_i = \frac{1}{m[\mu(E_0) \csc \Phi_1 + \mu(E_i) \csc \Phi_2]}
\]
and

\[ I_i = \frac{I_0 K_i W_i}{[\mu(E_0) \csc \Phi_1 + \mu(E_i) \csc \Phi_2]} \] (8)

Portable energy-dispersive X-ray fluorescence (EDXRF) spectrometers are becoming very popular in many fields for the on-site analysis of elements. This is mainly because EDXRF is a nondestructive, multielemental technique that is extremely well suited for the analysis of any material.

An EDXRF spectrometer mainly consists of an X- or γ-ray excitation source, an X-ray detector with electronics, and a pulse height analyzer. Recent technological developments have resulted in small, low-power, dedicated X-ray tubes, thermoelectrically cooled semiconductor detectors, and small pulse height analyzers. Therefore, completely portable EDXRF spectrometers are available that can be assembled on-site, having the size of a book and a weight ranging from as light as 500 g (using a radioactive source) to a few kilograms (using an X-ray tube). These spectrometers can be employed for on-site analysis in various fields, such as works of art, alloys, soil, environmental samples, forensic medicine, paper, waste materials, mineral ores and their products, or anywhere a portable apparatus would be required.

This paper reviews the present status of the development and application of EDXRF portable systems. The various components of a portable system are described: the radiation source, i.e. small, low-power, dedicated X-ray tubes or alternatively radioactive sources that emit X-rays or low-energy γ-rays; and X-ray detectors, i.e. scintillators, proportional gas counters and semiconductor detectors, with special emphasis on the recent thermoelectrically cooled X-ray detectors: Si-PIN (silicon positive–intrinsic–negative), Si-strip and CZT (cadmium–zinc–telluride).

Commercial systems are considered, and finally the most common and significant applications are described.
simultaneously with little or no sample preparation. EDXRF analysis simply consists of irradiating a sample with X- or γ-rays and of detecting the secondary X-ray spectrum emitted by the sample itself. Each element emits a typical set of X-ray lines and is characterized by their energy. The X-ray spectrum is therefore composed (at least theoretically) of as many lines as the elements composing the sample. The intensity of each line is proportional in some way to the concentration of the elements.

The sample also scatters (both coherently and incoherently) the incident radiation, generating lines due mainly to Rayleigh (coherent) and Compton (inelastic) scatterings.

An apparatus for EDXRF analysis consists of an X- or γ-ray excitation source, an X-ray detector with electronics, and a multichannel analyzer. Portable “laboratory” systems can be assembled, and can be employed for on-site analysis in various fields such as analysis of works of art, alloys, environmental samples, forensic medicine samples, paper, waste materials, ferrous metal mineral ores and their products, etc.

Recent technological developments have resulted in both small-sized, low-power X-ray sources and small, thermoelectrically cooled semiconductor detectors.

This paper reviews the present state of development and application of EDXRF analysis, using miniature X-ray tubes and radioactive X- or γ-rays for excitation, and scintillation, gas and semiconductor detectors for detection. Special emphasis is given to thermoelectrically cooled X-ray detectors.

### 2 X-RAY SOURCES

For portable EDXRF equipment, X-ray tubes or radioactive sources may be employed.

An X-ray tube typically emits bremsstrahlung radiation with energy from zero (theoretically) to the value (in keV) of the maximum tube voltage, plus characteristic X-lines due to the anode material (see Table 1).

In this section the characteristics of X-ray tubes and radioisotopes emitting X- or γ-rays for excitation, and scintillation, gas and semiconductor detectors for detection. Special emphasis is given to thermoelectrically cooled X-ray detectors.

### 2.1 X-ray Tubes

It should be noted that a 35–50 kV X-ray tube is adequate for the excitation of almost all elements of the periodic table, being able to excite K-lines of elements up to Z = 60 and L-lines of heavier elements.

* The X-ray tube current determines the minimum detection limit (MDL). This parameter is also dependent on the geometry, the sample, the elements to be analyzed, the collimation, and so on. (For further details, see Cesareo.)

In the last few years, small-sized and low-powered X-ray tubes of various anode materials have been produced expressly for EDXRF analysis. Manufacturers include Oxford Analytical Systems Division, Scotts Valley, CA, USA; Hamamatsu Photonics KK, Hamamatsu City, Japan; and EIS-XRS, Rome, Italy. The low cost of these tubes allows the use of various dedicated X-ray tubes for the different problems.

Table 1 lists a series of different tubes, according to their characteristics (voltage, current, and anode material) that are optimized for various elements. Typical sizes of X-ray tubes for EDXRF analysis are:

- a length of about 10–15 cm;
- a diameter of about 3–5 cm;
- a window (of beryllium or glass) of 1.5–2 cm diameter;
- a weight of about 200–500 g.

Recently, a micro X-ray tube was designed and constructed explicitly to replace small, radioactive sources in portable gauging, fluorescence and imaging devices (X-Ray & Specialty Instruments Inc., Ann Arbor, MI, USA). This tube has a maximum voltage of 35 kV, a
maximum power of 3 W, anode materials of Mo, Cu, W and a 0.25-mm diameter window of Be. It is a cylinder of length 8 cm and diameter 8 mm.

Photon output from an X-ray tube of the type described in Table 1 depends on many parameters, such as voltage, current and anode material. Typical outputs are 3–5 orders of magnitude larger than those of the radioactive sources. A typical small-size, low-cost X-ray tube for portable EDXRF systems is shown in Figure 1.

### 2.2 Radioactive Sources

α-, β-, X- and γ-ray sources may be employed for EDXRF analysis. Generally, they are characterized by their small size and low photon output compared with X-ray tubes and may be usefully employed for portable EDXRF systems.

α-ray sources are suited to the analysis of low atomic number elements. Those most used are 244Cm, with a half-life of 17.8 years and emission of 5.76 and 5.81 MeV α particles, and 210Po, with a half-life of 138 days and emission of 5.3 MeV α particles. Both are available from, for example, The Radiochemical Centre, Amersham, UK.

β-ray sources can also be employed both for direct EDXRF excitation of a sample and for producing bremsstrahlung radiation in a target to successively excite the sample. Typical sources of the first type are 22Na, 86Kr and 63Ni, with half-lives of 2.6, 10.7 and 100 years, respectively, and emissions of 0.55, 0.67 and 0.066 MeV β− particles. Typical sources of the second type are 147Pm (with a zirconium target) and 3H (with a titanium target), with half-lives of 2.6 and 12.4 years, respectively, and emitting photons up to 225 keV and 19 keV, respectively.

Few radioactive sources emitting X- or γ-rays are used for EDXRF analysis; some are listed in Table 2, and typical radioactive sources and excitation geometries are shown in Figure 2. The sources detailed here are available from The Radiochemical Centre, Amersham, UK.

A range of elements that can be usefully analyzed with the various radioactive sources and X-ray tubes is shown in Figure 3.

Radioactive sources for EDXRF analysis are much smaller than X-ray tubes. However, the energy of these sources cannot be changed. Moreover, their output is often not adequate for an efficient excitation. Additionally, X-ray tube output can be monochromatized at various energies using proper filters. Finally, the costs of an EDXRF tube are currently comparable to those of a radioactive source.

3 X-RAY DETECTORS

In the past, portable EDXRF analyzers traditionally involved the use of scintillation or proportional gas detectors, while laboratory systems typically used nitrogen-cooled semiconductor detectors, such as Si(Li) and HPGe (hyperpure germanium) (available from EG & G Ortec, Oak Ridge, TN, USA). X-ray scintillation detectors, such as NaI(Tl), CsI(Tl), are characterized by large areas but have very poor energy resolution, while proportional gas counters filled with neon, argon, krypton or xenon have better energy resolution as well as a large useful area. Both are relatively cheap (approximately US $1000–2000).

In the last few years there has been a true revolution in the field of X-ray detectors. In fact, thermoelectrically cooled Si-PIN, Cd$_{1-x}$Zn$_x$Te (CZT) and HgI$_2$ detectors (available from AMPTEK Inc., Bedford, MA, USA) have been substituted for many applications, especially for portable apparatus, scintillation or proportional gas counters, or nitrogen-cooled Si(Li) and HPGe detectors.

The thermoelectrically cooled Si-PIN detector has a thickness typically of about 300 µm which makes this detector useful up to X-ray energies of 30 keV, and an energy resolution of about 250 eV at 5.9 keV (AMPTEK Inc., Bedford, MA, USA). The HgI$_2$ detector has a thickness of a few millimeters, sufficient for an efficiency of about 100% in the whole range of X-rays. It typically has an energy resolution of about 200 eV at 5.9 keV (XSIRIUS Inc., Camarillo, CA, USA).

Figure 4 shows the energy resolution versus energy of scintillation detectors, proportional gas counters, Si-PIN, CZT, Si(Li) and HPGe detectors in the X-ray energy range.

The only present limitation of the new thermoelectrically cooled Si-PIN and CZT detectors in their useful energy range is the reduced area, which limits the efficiency of the system. If high efficiency is required, or only one element is to be analyzed, larger-area detectors can be used, such as proportional gas counters or HPGe.

4 PORTABLE ENERGY-DISPERSIVE X-RAY FLUORESCENCE SYSTEMS

Portable systems are widely used in many circumstances to monitor one (or several) element(s), or to look at the
PORTABLE SYSTEMS FOR ENERGY-DISPERSIVE X-RAY FLUORESCENCE

Figure 3 Range of elements that can be analyzed using (a) radioactive sources and (b) X-ray tubes with different anodes, showing excitation of K- and L-lines.

concentration of an element to indicate the quality of a particular technological process.

Several different combinations of X-ray sources and detectors can be constructed and are generally available on the market:

1. radioisotopic sources coupled to scintillation or gas proportional detectors;
2. radioisotopic sources coupled to thermoelectrically cooled semiconductor detectors;
3. X-ray tubes coupled to scintillation or gas proportional detectors;
4. X-ray tubes coupled to thermoelectrically cooled semiconductor detectors.

Figure 4 Energy resolution (in keV), as the full width at half-maximum (fwhm) of the X-ray peak, versus energy for different detectors. From top to bottom: a NaI(Tl) scintillator, a proportional gas counter, a thermoelectrically cooled semiconductor detector and a nitrogen-cooled semiconductor detector. The Kα energy difference of contiguous elements is also shown.

4.1 Portable Systems Based on Radioisotopic X-ray Sources and Scintillation or Gas Proportional Detectors

Scintillation detectors (typically NaI(Tl)) have a high efficiency, due to their large sensitive areas. However, the energy resolution is so poor that this detector can only be used with filters. Balanced filters placed between the sample and detector selectively transmit the X-rays of a given element, increasing the sensitivity of the system. A complete description of the method of balanced filters is given by Rhodes and Watt.

For example consider filters of nickel and copper, having their K-shell absorption edges at 8.33 and 8.98 keV respectively, just below and above the energy of Kα X-rays of zinc (8.63 keV). Calibrating the masses per unit area of the filters to have the same transmission outside the zinc Kα X-rays energy, a “pass band” filtering system is produced, and the difference in the count rates using the two filters is proportional to the intensity of fluorescent zinc X-rays. Filter transmission is therefore different only in the energy window enclosing the zinc Kα X-rays. The technique is thus highly selective to the zinc Kα X-rays, but the sensitivity is poor compared with that obtained with detectors with sufficient energy resolution to isolate the X-rays of the element to be analyzed.

The balanced filters method is also useful when coupled to a gas proportional detector. These have the advantage over semiconductor detectors in that they have a larger sensitive area. Their energy resolution is poor,
although better than that of scintillation detectors, but not sufficient to separate Kα X-rays of contiguous elements (see Figure 4). The higher count rates obtainable with these detectors lead to shorter analysis times but an EDXRF system based on these detectors can only be employed in applications in which few elements are to be analyzed, the poor energy resolution is not a limitation, and possible overlaps from adjacent Z elements are not involved. There are various types of gas proportional detectors where the selection of the filling gas (neon, argon, krypton or xenon) is especially important. This selection should be made according to the excitation source and to the element or elements to be analyzed.\(^{(3)}\)

There are many portable analyzers based on the use of radioactive excitation sources and scintillation or gas proportional detectors. These include the Outokumpu portable elemental analyzer, which is based on a gas proportional detector (Outokumpu Oy, Espoo, Finland); the Amdel system, which is based on the use of a scintillation detector (Australian Mineral Development Laboratories, Eastwood, Australia); and the Columbia Scientific (Austin, TX, USA) and Oxford Instruments (Abingdon, UK) systems, which use a gas proportional detector.

On-line analysis systems based on the use of radioisotope X-ray sources and scintillation or proportional gas counters have been listed by Watt,\(^{(15)}\) who also described their applications, such as in determining the metal content of mineral slurries and mineral powder, sulfur in oil, calcium in raw cement mix, iron and chromium in ore, and tin in galvanizing solutions.

### 4.2 Portable Systems Based on Radioisotopic X-ray Sources and Thermoelectrically Cooled Semiconductor Detectors

Thermoelectrically cooled semiconductor detectors (Si-PIN, CZT, and HgI\(_2\)) generally have sufficient energy resolution to resolve the fluorescent X-rays of adjacent X-rays (see Figure 4). There are only a few cases of overlap where resolution of X-ray peaks is difficult (Cu Kβ and Zn Kα, As Kα and Pb Lα, and a few others). The small sensitive area of these detectors is their main limitation, but it may be compensated for by the large solid angle between the sample and detector.

As observed in section 3, the Si-PIN detector is the best one currently available up to about 25–30 keV. At higher energies the intrinsic efficiency is poor, due to the limited thickness of these detectors (about 300 μm). In this region the CZT detector can be employed, or the HgI\(_2\) detector. The first has a poorer energy resolution, and both have the problem of “escape peaks”, due to Cd and Zn in the first case and to Hg and I in the second.
4.3 Portable Systems Based on X-ray Tubes and Scintillation or Gas Proportional Counters

This combination has never been used, because combination of a high-intensity source with a high-efficiency detector would be illogical.

4.4 Portable Systems Based on X-ray Tubes and Thermoelectrically Cooled Semiconductor Detectors

The coupling of a high-intensity flexible source as the X-ray tube with a high-resolution detector (for example Si-PIN) in our opinion is the best possible current system for in situ XRF analysis. The combination of the appropriate X-ray tube (in terms of anode, high voltage, current, collimation) coupled to the corresponding X-ray detector (material, thickness of the material and of the Be-window) and sample geometry gives the best results.

Portable systems based on the use of an X-ray tube coupled to a thermoelectrically cooled semiconductor detector are manufactured and supplied by EIS-XRS (Rome, Italy), as one example. Various combinations of tubes (high voltage, anode material, current) and detectors (Si-PIN, CZT) are available, and should be selected according to the planned application.

A portable EDXRF system based on the use of an X-ray tube and a thermoelectrically or nitrogen-cooled Si detector is produced by Kevex Spectrace (model Spectrace 9000) and specifically dedicated to soil analysis.

5 EXAMPLES OF APPLICATIONS OF PORTABLE ENERGY-DISPERSIVE X-RAY FLUORESCENCE SYSTEMS

5.1 Analysis of Sulfur and Chlorine in Environmental Samples and in Works of Art

Sulfur in coal, oil and gasoline is a source of pollution, and strict environmental controls are now in place to limit sulfur release into the atmosphere. In the past, sulfur was freely released and formed deposits on monuments, frescoes and so on, causing damage. Chlorine is present as NaCl in the air coming from the sea and its deposits cause corrosion on monuments.

A portable system has been constructed by EIS-XRS, for the analysis of sulfur and chlorine in solids and liquids. This system is based on a Ca-anode X-ray tube, working at 6–8 kV, coupled to a thin Be-window Si-PIN detector. The Ca-tube emits 3.7 keV X-rays that excite S and Cl X-rays with high efficiency without directly exciting X-rays of Ca, which is by far the most common element in lapideous monuments and frescoes (Figure 7). A Pd-anode Oxford X-ray tube can also be employed for the same purpose. In this case, the tube works at 4–5 kV, emitting Pd L-lines at 2.84 and 3 keV.

MDLs of about 0.02% and 0.1% are obtained in the analysis of S and Cl in calcareous surfaces respectively, while much better results are obtained for oil and gasoline.

5.2 Analysis of Works of Art

In the analysis of works of art (monuments, statues, frescoes, paintings, alloys, etc.) the portability of the system is a mandatory requirement, because in nearly all cases it is impossible to take the work of art to the laboratory. However, with a portable EDXRF apparatus, it is generally possible to take it to the work of art, to the museum, to the excavation, and so on.

Examining the analytical problems related to the study of works of art, one can deduce that in the great majority of the cases the elements to be analyzed are in the range between Z = 16 (sulfur) and Z = 50 (tin). This range corresponds to an excitation energy between 3 and 35 keV. High Z elements (gold and lead) are included in the same energy range, because the L-lines are more usefully analyzed.

Portable systems have been assembled by us since 1972, starting with the analysis of paintings and ancient alloys (gold, bronzes, and brasses). A $^{147}$Pm radioactive source was employed, which is characterized by a useful bremsstrahlung spectrum ranging from 15 to 45 keV approximately, plus a xenon gas proportional detector and a single-channel analyzer.

Recently, a new portable apparatus was manufactured to our design by EIS-XRF (Rome, Italy). It includes a 40-kV X-ray tube and a Si-PIN or CZT detector. The
Figure 8 EDXRF system employed by the authors for the analysis of the golden altar of the basilica of St. Ambrogio, Milan. From left to right: the measuring head, comprising an Oxford W-anode X-ray tube and a Si-PIN detector, the bias supplies for both tube and detector, and the multichannel analyzer.

The system described above has been used for the analysis of gold samples, paintings, and bronzes (Figure 8). The first detector may be employed up to about 20 keV, the second at higher energies. The system described above has been used for the analysis of gold samples (Figure 8), paintings (Figure 9), and bronzes (Figure 9).

5.3 Analysis of Alloys
As observed in section 5.2, bronzes, brasses, gold and silver alloys have been analyzed using an EDXRF apparatus. Rapid sorting of alloys is required in many areas of the metal industry, such as fabrication, inventory control and the sorting of scrap. Some common alloy groups include nickel and copper alloys, stainless steels, special steels, precious metals, and so on. The main requirements of analysis equipment for alloy identification are portability, speed and reliability of identification. For the alloys, an accurate quantitative determination is generally required, and therefore sufficient standard samples are needed to calibrate the apparatus. Piorek and Rhodes have shown that a 111 MBq $^{109}$Cd source and a high-resolution proportional counter are adequate to identify many alloys.

Currently, better results can be obtained by using a portable system of the type described in section 5.2, which is adequate for the analysis of Ni, Cu, Fe, Cr/Mo, Au, Ag and other alloys.

TN Technologies (Round Rock, TX, USA) has developed portable EDXRF systems (Metallurgist XR) for the analysis of alloys. It uses 45 mCi $^{55}$Fe or 5 mCi $^{109}$Cd radioactive sources and a high-resolution thermoelectrically cooled HgI$_2$ detector, and may be employed for the analysis of low-alloy steel, Fe, Cr, Ni, Co alloys, brasses and bronzes, and Al alloys. The weight of the measuring head (source plus detector) is 1.1 kg (see Figure 6).

5.4 Analysis of Lead in Paint
One of the more serious public health hazards, which particularly affects children, is related to lead-based poisoning from the paint found in many old houses.
The estimated number of apartments in New York City alone that may be affected by this hazard is greater than 300,000, and they are mainly occupied by low-income families. Recent legislation in the US provides specific requirements for new inspection procedures in federally funded housing programs as well as for the disclosure of information and inspections during the sale and transfer of all private residential houses and apartment units constructed prior to 1978. (Allowable lead content in paint was significantly reduced after 1978.) Inspection companies and state and federal agencies, which are charged with the responsibility of supervising compliance with this legislation, employ EDXRF hand-held instruments for on-site detection of lead concentration levels in paint. An abatement plan to eliminate paint poisoning hazards can be required for concentrations of lead in paint equal to or exceeding 1 mg cm$^{-2}$. Some states have adopted even more stringent standards.

This application demonstrates the necessity of using K X-rays in the determination of lead concentration. The lead L X-rays can only serve as supplementary information, due to their strong attenuation by paint overlays. The high energy of the Pb K X-ray lines (75, 85 keV) imposes additional restrictions on the choice of a detector and an excitation source. High atomic number compound semiconductor detectors such as CdTe, CZT or HgI$_2$ are favored in this application because of their good detection efficiency, high-energy resolution, and operation near room temperature. Also, excitation radioactive sources such as $^{57}$Co or $^{109}$Cd are more practical for hand-held instruments than X-ray generators, which are difficult to miniaturize for these relatively high X-ray energies. Table 3 lists portable instruments used to measure lead in paint and outlines their main characteristics.

### 5.5 Analysis of Environmental Samples

The concentration of air particulates is determined by collecting a large volume of air through a filter paper, which is then submitted to EDXRF analysis. Rhodes showed that a laboratory system combining an appropriate radioactive source and a nitrogen-cooled semiconductor detector allows the determination of elemental concentrations of many trace elements. A sensitivity of about 0.03 g cm$^{-2}$ on the filter, corresponding to 6 ng m$^{-3}$ of air over a 10-min period, was obtained. A portable system composed of an X-ray tube and a Si-PIN detector will give approximately the same results, because the smaller area of the detector is compensated for by a higher-intensity source.

On-line and in situ analysis of industrial waste is also important for environmental purposes. A dedicated portable system can be easily constructed, according to the element or elements to be analyzed and their concentration. In the case of only one element, electronics composed of a single-channel analyzer and a digital ratemeter can be constructed with a continuous output of data.

### 5.6 Analysis of Soil

In situ analysis of metals in soil, mainly S, K, Ca, Ti, Mn, Fe, Zn and others, can also be carried out with a portable system composed of a Mo-anode low-voltage X-ray tube and a thin Be-window Si-PIN detector.

Additionally the analysis of elements contained in fertilizers, and in substances introduced into the soil (P, S, Cl, K and others) can be carried out with the same portable apparatus.

Portable EDXRF systems for soil analysis are described in sections 4.2 (NITON XL-700) and 4.4 (Kevex Spectrace 9000).

### 5.7 Underground Determination of Heavy Metal Contaminant Concentrations

The site characterization and analysis penetrometer (SCAPS) XRF sensor provides XRF spectra on soil in situ down to depths of over 45 m. Its purpose is to measure heavy metal contaminant concentrations directly in the soil. Cone penetrometry, which was developed almost 100 years ago to explore soil strata for railroad bed construction, is an excellent method for bringing a variety of sensors into contact with subsurface

soils. Unlike other field-portable XRF instruments, the sensor uses an electrically excited X-ray tube as a source and is protected by a rugged but X-ray-transparent window. These features provide an instrument with excellent capabilities and which will withstand direct contact with underground soils. The probe and methods were developed by W.T. Elam of the US Naval Research Laboratory in conjunction with J.V. Gilfrich and K.R. Hudson of SFA, Inc., and B. McDonald of the University of Toledo.

The XRF metal sensors consist of three subsystems: the actual below-ground probe (Figure 10), the umbilical cable and the above-ground electronics package. The probe contains the X-ray source (up to 30 kV), detector (Si-PIN) and preamp, appropriate X-ray optics, the mounting system and the rugged X-ray window. The above-ground electronics package contains the X-ray tube power supply with safety interlocks, the driver electronics for the detector and the multichannel analyzer.

5.8 The Mars Mission

On July 4, 1997, a portable EDXRF apparatus constructed for analyzing rock landed on Mars. It employs a $^{244}\text{Cm}$ $\alpha$ radioactive source and an AMPTEK XR-100 X-ray detector. The apparatus is shown in Figure 11, and a typical X-ray spectrum is shown in Figure 12.

5.9 General Applications

A portable apparatus (Spectrace 9000 Field Portable XRF Analyzer) developed by TN Technologies (Round Rock, TX, USA) may be applied to analysis of elements from sulfur to uranium, with concentrations from parts per million to percentage levels. This apparatus is characterized by various radioactive sources ($^{55}\text{Fe}$, $^{109}\text{Cd}$ and $^{241}\text{Am}$) according to the elements to be analyzed, by a high-resolution HgI$_2$ detector, and software. The analyzer is a 2000-multichannel analyzer with software that automatically executes a selected menu. Each data acquisition procedure includes selection of source,
acquisition time, computation method and display of analysis results.

1 Introduction

1 SOME CONSIDERATIONS THAT THE X-RAY FLUORESCENCE ANALYST SHOULD BE AWARE OF

In XRF the sample preparation procedure is at least as important as an analytical technique and it strongly influences the final quantitative result. Any method of specimen preparation must give specimens that are reproducible and, for a certain calibration range, have similar physical properties (e.g. comparable mass attenuation coefficient, density, particle size and particle homogeneity). Improper selection of a sample from the bulk or improper sample preparation can cause large systematic errors to be introduced; therefore the following principles should be considered as a rule:

- before any sample preparation is selected, one should think of the purpose of analysis;
- specimen preparation should be avoided as much as possible;
- a method should be selected that is cheap and rapid and does not introduce additional errors or contamination;

This article is a comprehensive review of sample preparation methods for various kinds of samples prior to X-ray measurement. Not only are commonly used methods presented but also included are some specific techniques for certain kinds of materials, with emphasis on more recent applications and developments.
• if possible, preference should be given to simple physical sample preparation methods such as drying, freeze-drying, homogenizing, pulverizing, cutting;
• an adequately prepared specimen must be representative of the material and homogeneous and have a flat, smooth surface;
• all standards and unknown samples must be presented for analysis in a reproducible and identical way;
• standards must have similar physical properties, such as mass attenuation coefficient, density, particle size, homogeneity, etc.;
• contamination control and blank specimen preparation should be readily implemented;
• loss of analyte elements (particularly halogens) should be considered;
• careful and accurate records must be kept of samples received for analysis;
• routine statistical testing should be a part of all laboratory procedures and goes under the category of quality assurance;
• accuracy should be controlled by using Standard Reference Materials.

3 PROBABILISTIC SAMPLING PROCEDURES

It is important to emphasize that good sampling is absolutely crucial to the meaningfulness of the ultimate analysis. Because every step is linked materially to all other steps, it is essential to plan in detail the complete sampling program, starting from field sampling and through to the specimen proceedings in a balance room, before the first test portion from the bulk sample is taken.

A crucial early step in a sampling procedure is splitting of a sample: in its simplest form the sample is divided into two equal (in every sense) parts, one of which is archived in case it is needed later. Splitting a granular material is a dynamic process that usually involves pouring. Pouring always causes segregation, so it is vital that the segregated particles always appear in each split in their original proportions, otherwise an extraction error occurs. The oldest method of splitting is coning and quartering. This is attractive for samples ranging from tens of kilograms to a few grams. Firstly, a granular sample is carefully poured vertically onto a clean surface in order to form a cone. The dynamics of correct pouring will ensure that coarser fragments are uniformly concentrated around the periphery of the cone and that the finer ones are uniformly distributed in the center. Then, the cone is quartered by precisely dividing it into four equal sectors vertically. This quartering must be done without generating a delimitation error.

For large samples containing tens of kilograms of material, alternate shoveling is preferred to coning and quartering. In this method, the primary sample is poured in a symmetrical pile onto a clean surface. The original pile is made into two nonoverlapping piles by shoveling from the original one. It is important that the shovelfuls all be the same size and that each new pile contains the same number of transfers. In practice, it is difficult to come out exactly even; therefore the size of the shovel must be small relative to the size of the pile. For further reduction in the size of the primary sample, one of the two new piles is chosen at random and the process is repeated. In this way, the sample is reduced to a size that can be reduced further prior to final grinding.

Another shoveling or scooping method that allows probabilistic sampling is the linear Japan cake. The sample from a previous stage is spread in a linear pile from which a single scoop can be extracted randomly in one motion. The pile is constructed by pouring back and forth along its design length. Several samples can be extracted in this way. The pile should be at least 25 times longer than the width of the scoop. Any material that the scoop pushes out of the pile has to be recovered to the sample. Pitard suggests that this method can be used even with small samples in the laboratory balance room.

The riffle splitter (or Jones splitter) is one of the best and simplest devices for splitting. It is a box containing an even number of adjacent chutes alternately inclined in opposite directions. When the primary sample is poured properly into the top of the splitter box, half of the sample passes through one set of chutes and half through the other. If the sample passes equally through all the chutes, no significant delimitation or extraction errors will be generated.

Sectorial splitters allow the sample to be split initially into more than two parts. In such a device normally several funnels are assembled together, with common sides forming the radii of a circle and their third sides forming the perimeter of the same circle.

4 SOLID SAMPLES

4.1 Metallic Specimens

XRF is one of the most common techniques for the analysis of samples in metal production and therefore the preparation of such a specimen should be fast, simple and reproducible. The most universally employed sample preparation procedures are cutting, milling and casting.

XRF analysis of metal samples mostly involves a relatively thin surface layer of the investigated specimen; therefore it must be representative of the bulk sample.
structure. The major surface preparation methods are machining (milling, turning), mechanical grinding, and polishing and etching. In any employed surface preparation technique, special care must be taken to ensure that no additional surface contamination is introduced. This care is particularly important in the case of a relatively soft metal such as aluminum, where particles of the grinding agent may penetrate to the sample surface during surface finishing. Selection of a suitable abrasive is sometimes very difficult, particularly when elements like Si, Al or Fe need to be determined. For instance, SiC and Al₂O₃ are very effective abrasives, but both contain elements of interest. In such cases electrolytic polishing or etching is recommended. After each grinding or polishing step it is important to ensure that the surfaces are kept clean; hence all traces of lubricant, cutting fluid or finger marks must be removed by cleaning with isopropyl alcohol prior to examination. Occasionally the surface of several metals is affected by corrosion, which progresses with time; therefore the best results are always obtained when analyzing a specimen without much delay after surface preparation.

When the surface of the specimen is too rough and common methods like polishing and milling are not effective enough, the samples can be prepared by pressing them into pellets with a hydraulic press at several hundreds of megapascals. With such a procedure most of the turnings are compacted into satisfactory smooth surfaces.

Selection of the most suitable surface preparation technique depends on the individual characteristics of an alloy or group of alloys. For example, hard alloys that are resistant to cutting and abrasion, such as cast iron, can be ground and pelletized prior to analysis. On the other hand, if the sample is composed of soft, malleable, multiphase alloys, the smearing effects of softer components like Pb and Al can cause problems. The soft elements will be enriched onto the surface and the fluorescent intensities of the softer phase increase, whereas those of the harder ones decrease. In such cases, when the sample surface is not representative of the bulk composition, electrolytic polishing or etching should be employed. For some archeological materials, the etching procedure might be too excessive because many inclusions are dissolved during etching. For bronze alloys the recommended etching reagent is a solution of alcoholic ferric chloride (120 mL of C₂H₅OH, 30 mL of HCl and 10 g of FeCl₃), whereas for brass alloys a solution of aqueous ammonium persulfate (100 mL of H₂O and 10 g of (NH₄)₂S₂O₅) is preferred. Ancient metals etch very fast; only a 5–10 s etching time is required.

A number of metals and alloys that are otherwise very difficult to deal with can be brought into solution in aqua regia (a mixture of one part concentrated HNO₃ with three parts concentrated HCl) with gentle heating to 60°C. Aqua regia is used to attack a number of metals (e.g. Pd, Pt, Sn, Ge) and alloys, including steels, alloys of Mo, Rh, Ir and Ru, and high-temperature alloys. The strength of this combination belongs to the formation of chloro complexes during the reaction, as well as to the catalytic effect of Cl₂ and NOCl. The effectiveness additionally can be improved if the solution is allowed to stand for 10–20 min before heating. Iron and vanadium ores and crude phosphates can be dissolved by this mixture, as well as some sulfides (e.g. pyrites and copper sulfide ores), although a part of the sulfur is lost as H₂S. Both HNO₃ and HCl are often used together in other proportions. So-called inverted aqua regia (mixture 3 : 1) is used to oxidize sulfur and pyrites. Another aggressive decomposition reagent is the combination HNO₃—HF. Here, the complexing effect of the fluoride ion is utilized and with this combination a number of metals (e.g. Si, Nb, Ta, Zr, Hf, W, Ti) and alloys (e.g. NbSn, AlCr, CaSi, CaSi) can be dissolved. However, some elements may be lost during the digestion step: elements like Se, Hg and Sn form volatile components with various kinds of acids and their combinations, samples treated with hot mixtures of HNO₃—HF—HClO₄ lose Se and Cr completely; and Hg, As, Ge, Te, Re, Os and Ru show particular losses. Another, rather new, technique is remelting of the sample. The original ferroalloy is ground to a grain size of 2 mm with a steel disk mill, followed by a W-mill, after previous crushing with a jaw breaker. Subsequently, the grained particles are mixed fairly with a W-mill, after previous crushing with a jaw breaker.

The analysis of semiconductors is often carried out by TXRF or synchrotron radiation X-ray fluorescence (SRXRF). However, there are also some interesting applications with XRF, such as the determination of Ni implantation in Si wafers, which can be measured directly with XRF simply by placing the wafer in the spectrometer. More difficult is the preparation of calibration standards for this application, which can be obtained in an unconventional way by spiking gelatin-containing Ni standard on parts of the Si wafer and drying prior to analysis. Irregularly shaped metallic specimens are prepared for analysis by embedding the piece in a special wax resin (e.g. acrylic resin and methyl acrylic resin). This block can be polished to appropriate surface smoothness by abrasives such as SiC and diamond paste, prior to analysis.
4.2 Powder Specimens

4.2.1 General

A common technique for geological, industrial and biological materials is the preparation of powders and pellets. Powdered specimens are prepared when the original sample is too heterogeneous for direct analysis or too brittle to form self-supporting disks or when a suitable surface finishing is not possible. The XRF analysis of powder samples requires particles in a uniform size range and with a small enough grain size to yield chemical homogeneity without absorption problems. Crushing, pulverizing and milling procedures may be used to achieve these goals. Additives (see section 4.2.2) are sometimes useful for proper grinding of powders; in general, 2–10% additive to aid in the grinding, blending and briquetting process is sufficient for most materials. Once the sample has been crushed, it is necessary to separate out the fraction that is too coarse for further treatment. Sieves are used for this step. The powder specimen must fit into the specimen chamber of the X-ray spectrometer. It is desirable to have the specimen in the shape of a round, flat disk. For this purpose, presses and dies are applied. Another possibility is to present them directly to the spectrometer as loose powders, packed in cells or spread out on film materials (the so-called “slurry” technique). The slurry technique works for water-insoluble materials. A water slurry is prepared out of a few milligrams of powder and a few milliliters of water. A turbulent suspension is made, followed by rapid filtration through a Nucleopore filter for example. This method results in fairly uniform thin layers suitable for XRF analysis.

Processing large bulk samples poses the most problems. The challenge is to pulverize the sample, to produce fine particles without contamination or fractionation, to homogenize the product and to split it into representative aliquots for study.

4.2.2 Grinding

One of the principal considerations in sample preparation methods is a reduction of sample particle size. For a routine trace XRF analysis a particle size of less than 62 µm is commonly accepted. Reduction of the sample particle size is commonly accomplished by grinding. Various methods for grinding samples are available. For routine work, manual grinding using a pestle and mortar (agate, corundum, mullite) is traditionally used, whereas for finer (1–10 µm) and controlled particle size a variety of mills are commercially available. When dealing with extremely small amounts of sample, hand grinding is the best option, although it is tedious and time-consuming. Materials that are difficult to treat, such as rocks and ores, can be prepared much faster and more efficiently after the addition of sodium stearate. It is found that manual grinding of inorganic aluminum silicate, for example, by using a pestle and mortar reduces the particle size to about 38 µm, which is acceptable even for X-ray diffraction (XRD) methods. In the case of coal samples prepared as a powder (5 g of sample ground in a wet chemical rotary swing mill together with 1 g of boric acid binder and 100 mg of sodium stearate), a grinding time of about 6 min will reduce the particle size to 50 µm. For materials that may be damaged or undergo alteration during size reduction, grinding is usually carried out under alcohol using a pestle and mortar. Grinding in liquid nitrogen (in an SPEX freezer/mill for example) may also be effective for materials like polymers and plastics. Mechanical grinders can also be used under dry and wet conditions. When grinding samples that are mixtures, different physical properties may lead to significantly different results with the different phases. Experience has shown that all grinding tools present a source of contamination; therefore the material should be selected carefully for a particular application. Agate, for instance, introduces traces of SiO₂, Mg and Ca to the specimen. This might be of less interest for geological materials, but for biological materials these blank values represent a major source of error.

4.2.3 Pelletizing

Pelletizing of the powder samples is required to reduce surface effects and to yield a better precision than the loose powders. In general, provided that the powder particles are less than 50 µm in diameter (300 mesh), the sample should be pelletized at 6–8 tons cm⁻². If the self-bonding properties of the powder are good, low pressures of perhaps up to 1–4 tons cm⁻² can be employed. High-pressure pelletizing in a die, or directly in a sample cup, often results in fracture of a pellet following removal of pressure from the die. It is sometimes necessary to add a binder before pelletizing to help form stable pellets and to prevent caking of the sample at the die surface. Binders are normally composed of light elements or organic materials and scattered X-rays increase the background of the spectrum. This effect can become important in the determination of trace elements in the low-atomic-number region, therefore the choice of the binding agent must be made with special care. It must be free from significant contamination and must have low absorption. As well as having good binder properties, it must not interfere with the elements being measured. The most useful binders are starch, cellulose, lucite, polyvinyl, urea, boric acid, graphite, etc. Liquid binders such as ethyl alcohol or
diethyl ether can be mixed with the sample manually, whereas powdered binders are recommended to be mixed mechanically to form a homogeneous mixture. A recommended procedure is the addition of 2–10% binder to the sample. Further stability can be achieved by spraying the pellet with a 1% solution of Formvar in chloroform.

4.3 Fused Specimens

Samples that do not go into solution easily or tend to remain heterogeneous after grinding and pelletizing are often treated by the technique of flux fusion. Probably the most effective way of preparing a homogeneous powder sample is the borax fusion method.\(^7\) In principle this involves fusion of the sample with an excess of sodium or lithium tetraborate and casting into a solid bead. Chemical reaction in the melt converts the phases present in the sample into glass-like borates, giving a homogeneous bead of dimensions ideal for direct placement in the spectrometer. Manual application of the technique is rather time-consuming, but a number of automated and semi-automated borax-bead-making machines are commercially available. The critical stage in this method is to control the ratio of sample to fusion mixture, because this governs several factors: the speed and degree of the chemical reaction, the final mass absorption coefficient, and the actual dilution factor applied to the analyte element. By using fusion aids (such as iodides and peroxides) and high-atomic-number absorbers (such as barium or lanthanum salts) as part of the fusion mixture, these factors can be controlled. Claisse’s original method proposed a sodium tetraborate/sample ratio of 100:1.\(^7\) In 1962 Rose et al.\(^8\) suggested the use of lithium tetraborate in a ratio of 4:1. A critical review on this subject was done by Bower and Valentine.\(^9\) The actual fusion reaction can be performed at 800–1000 °C in a crucible made of Pt, Ni or SiO\(_2\). All of these materials suffer from the disadvantage that the melt tends to wet the sides of the crucible and it is impossible to achieve complete recovery of the fused mixture. By using graphite crucibles this problem can be partially overcome, but the best characteristics are achieved in a crucible made of Pt and 3% Au.

The most severe disadvantages to the fusion techniques are the time and material costs involved and the dilution effect of the sample, which makes it often difficult or even impossible to determine trace elements in the specimen. For this reason the low-dilution fusion technique was developed, where the flux/sample ratio is 2:1. Mostly LiBO\(_2\) is applied as a flux, because it is more reactive and forms fluxes with higher fluidity. Many useful recipes for fusions are given in a recent book.\(^2\)

5 LIQUID SPECIMENS

5.1 Direct Methods

In most spectrometers, liquids can be analyzed as such, even under a pressure that is slightly below atmospheric. Special care should be taken that the analyzed surface remains reproducible and that no gas bubbles are formed under the influence of the X-rays, e.g. in acid solutions. For the analysis of liquid specimens, special cells can be made of stainless steel, polyethylene or polytetrafluoroethylene (Teflon\(^8\)). These cells are covered by Mylar or Kapton foils with a thickness of 3–6 µm. Sometimes, microporous films are applied. Because the most conventional spectrometers irradiate the sample from below, the support film attenuates the signal from the elements of lower atomic number, as well as introducing a significant blank. Absorption by air also poses a problem for measurements in the low-atomic-number region. Liquids are well suited for reducing matrix effects and for adding various amounts of internal standards. However, in contrast to standards prepared by fusion or pelletizing, liquid standards deteriorate with time due to adsorption and precipitation effects.

However, the major drawback of liquid analysis is the high background level due to X-ray scattering. This makes it difficult, or sometimes even impossible, to determine light elements at low concentrations. In general, direct analysis of aqueous samples leads to limits of detection in the part-per-million range, which is not satisfactory for most natural water analysis applications. Consequently, it is necessary to remove the matrix to improve detection limits.

5.2 Preconcentration Methods

In many cases (e.g., environmental aqueous samples), some preconcentration technique is to be applied to the water samples before analysis. The sample resulting from preconcentration is usually in the form of a thin sample and, as such, meets the thin-film criterion. Consequently, the conversion of XRF data to element concentration is a rather simple procedure. Many preconcentration methods for the analysis of water by X-ray spectrometric techniques have been proposed so far. A comprehensive overview of this subject, dating back to 1982, was given by Van Grieken.\(^10\)

For samples of low salinity or hardness, preconcentration can be accomplished easily by simple evaporation. To achieve detection limits at the part-per-billion level, evaporation of about 100 mL of water is necessary. A large water sample also can be freeze-dried, and the evaporation residue can be pelletized, possibly after mixing with organic binder to reduce matrix effect variations.
Freeze-drying of 250 mL of waste water on 100 mg of graphite followed by grinding and pelletizing of the residue can lead to detection limits of a few micrograms per liter. In the evaporation residue, all nonvolatile elements are collected quantitatively and the risk of contamination is minimal.

Unfortunately, taking samples to dryness causes some experimental problems, such as fractional crystallization, splashing, etc. For these particular reasons, preconcentration by evaporation has not found a great deal of application except when combined with some special techniques like TXRF. However, sometimes simple evaporation of the solution straight onto confined-spot filter paper can be sufficient, as is employed successfully in the so-called microdroplet sample preparation method. The advantage of the method is a rapid sample treatment with a small amount of sample for X-ray measurement. On the other hand, the disadvantage of the method is that the elemental distribution through a filter paper is heavily affected by the drying condition of the filter paper, due to condensation of the analyte on the surface of the filter material. Such experimental errors, derived from the drying conditions of the filter paper, can be minimized by drying at 10°C and by using an internal standard. In addition, a new thin-film sample support was designed to accumulate a small amount of sample solution (about 50 µL) into a small spot. By a special surface treatment, this newly developed film (AP2, Process Analytics) creates approximately an 1.5-mm hydrophilic spot in the center of a hydrophobic field, resulting in a low scattering of X-rays from the matrix of the sample. The reported precision of the method is 2–9% for transition metals of X-rays from the matrix of the sample. The reported recently, such as on-line process control in industry using a continuous flow of sample through a sample chamber. It appears, also, to be a well-suited technique to accumulate a small amount of sample solution (about 50 µL) into a small spot. By a special surface treatment, this newly developed film (AP2, Process Analytics) creates approximately an 1.5-mm hydrophilic spot in the center of a hydrophobic field, resulting in a low scattering of X-rays from the matrix of the sample. The reported precision of the method is 2–9% for transition metals of X-rays from the matrix of the sample.

Another effective method involves concentration of a litre of water, for example, on a cation-exchange resin column and direct analysis of the resin by EDXRF. With this procedure, trace metal contamination of a few parts per billion is easily determined in drinking water. Anion-exchange filters may be used to concentrate or selectively remove a particular component. An example is the determination of Cr³⁺ and Cr⁶⁺. In acid medium, an anion-exchange filter paper will collect Cr⁶⁺, whereas Cr³⁺ passes through. Subsequently, the toxic Cr⁶⁺ can be analyzed directly on the filter paper.

Another useful method for multielement trace analysis of aqueous samples is co-precipitation. Various co-precipitation agents have been proposed in the literature for XRF. By far the most appropriate are sodium diethylthiocarbamates and ammonium pyrroldine dithiocarbamate (APDC), or a combination of both. The carbamates are particularly attractive because of the low solubility of their metal chelates. The recommended procedure involves 100–500 mL of the water sample (adjusted to pH 3.5) and the addition of 2 mL of a 1% aqueous solution of APDC. After 40–60 min of stirring, the precipitate is filtered onto a 0.22- or 0.4-µm pore-size Nucleopore membrane and the loaded filter is analyzed after drying. The detection limits can be below 1 µg L⁻¹ for a suite of cations.

It should be emphasized that chemical preconcentration inherently holds some risks for sample contamination and may be inaccurate because of the possibly different behavior of the different chemical species of an element. Naturally occurring organic material might interfere with the co-precipitation reaction. Bringing the sample to pH 3.5 constitutes a compromise in this respect: much of the organic material will be destroyed already and adjusting the sample to a lower pH does imply more contamination by the acid. Furthermore, many elements are not collected in the proposed way, e.g. alkali and alkaline-earth ions and Mn²⁺ (except at very high pH). Also, some species of elements, such as Cr³⁺, might escape precipitation. Additionally, preconcentration can be labor-intensive and time-consuming.

Solid materials in aqueous samples must be filtered out through, for example, Nucleopore or Millipore membranes with 0.4-µm pore size (this is the conventional limit between “dissolved” and “particulate” matter in environmental waters), dried, and the filter analyzed as a solid.

The XRF analysis of liquids increases in importance from year to year. Numerous applications have been reported recently, such as on-line process control in industry using a continuous flow of sample through a sample chamber. It appears, also, to be a well-suited
SAMPLE PREPARATION FOR X-RAY FLUORESCENCE ANALYSIS

6 BIOLOGICAL SAMPLES

Solid biological materials are generally heterogeneous. Therefore, drying, powdering, homogenizing and homogeneity testing might be necessary before preparing the samples for measurement. Various subsequent treatments of biological materials include lyophilization, ashing and wet digestion. The digestion method should be optimized and the recovery of the elements and precision of the procedure should be thoroughly tested.

Specimen preparation for XRF of plants, leaves and vegetation is simple and fast. The representative samples are collected (approximately 5 g), dried at 85 °C, pulverized and pressed into pellets without any contamination. Usually 10–20 elements can be determined quantitatively in a matter of minutes.

Most human and animal tissues are very soft and hence they must first be stabilized and strengthened before sections can be cut. One possibility is to freeze-dry the tissue and pulverize it at liquid nitrogen temperatures. A small amount of that powder can be fixed to a thin membrane with a solution of 1% polystyrene in benzene and measured. Frozen organic tissue can be cut with a microtome, and if the sections are not too thin they can be dried and irradiated as self-supporting targets. To quantify the results, it is sufficient to add an internal standard before the analysis and to determine the dry mass of the sections after analysis.

The interest in clinical applications increases from year to year. In vivo analysis, particularly for Pb, is a major issue for XRF. The direct determination of Pb in bone gives an indication of the ongoing accumulation, whereas conventional blood studies only reflect the recent exposures. Other heavy metals of interest are As, Cd, Hg and U. Further in vivo investigations dealt with the concentration of various elements in different organs, mainly in the field of kidney, liver and lung research. However, the sensitivity and detection limits of the in vivo applications are still rather poor.

Other applications of XRF analysis include hair, teeth, nails, biological liquids (e.g. blood and serum), drugs and medicines. Blood samples, for example, can be pipetted in 100-μL portions onto filter paper. Serum samples can be treated almost in the same way but instead of filter paper, polypropylene foil should be selected as a carrier.

To avoid losses of volatile components, urine and blood samples need to be dried in a refrigerator at temperatures of about 2–4 °C. Detection limits of between 1200 μg L\(^{-1}\) for Ca in urine and 50 μg L\(^{-1}\) for Sr in blood are achieved with such treatment.

As for the preconcentration of traces from water samples, various kinds of co-precipitation or ion-exchange methods have been proposed for biological samples. For example, a very low concentration of Cr (0.3 mg mL\(^{-1}\)) in plasma could be determined by complexation with APDC and extraction with methyl isobutyl ketone. After evaporation of organic solvent, the residue is dissolved in acid and deposited on a thin polycarbonate foil.

Hair samples (0.1 g) can be digested with a 1 : 5 mixture of HClO\(_4\) and HNO\(_3\) in a Teflon\(^{®}\) bomb and the trace elements are co-precipitated using APDC at pH 3–4. In this way, elements such as Fe, Ni, Cu, Zn and Pb could be determined down to 0.4 μg g\(^{-1}\). The same limits of detection could be achieved if, for example, 1 g of hair sample is pelletized with 0.1 g of CaO and 20 g of cellulose.

The wet digestion methods, by microwave or high-pressure ashing, are very effective. With a mixture of HNO\(_3\), H\(_2\)O\(_2\) and HF most organic material can be attacked. Even more effective is a combination of HNO\(_3\) and HF because silicates in organic materials are also dissolved. Solvents HClO\(_4\) and H\(_2\)SO\(_4\) should not be mixed due to the possibility of explosion when heating. Care should be taken to work, whenever possible, in closed conditions to avoid contamination and/or losses of elements. The combination of microwave and pressure digestion allows the quantitative recovery of elements that may be volatilized in open digest (like Ge, Se, Hg, Pt, Os and Ir), as well as the recovery of rare trace metals (Pt, Os and Ir) to the part-per-billion level in solid samples, even in the extremely difficult digestion of organic material. For a basic understanding of microwave acid digestion theory, including safety guidelines and dissolution methods for geological, metallurgical, botanical, biological, food and other samples, we recommend the professional reference book edited by Kingston and Jassie.
7 ATMOSPHERIC PARTICLES

XRF is frequently invoked for trace analysis in air pollution studies. In the air, trace elements are almost exclusively in the particulate phase at typical concentrations of 50–500 ng m\(^{-3}\). By simply drawing a large volume of air through a filter, large preconcentration factors are easily achieved. Adequately loaded filters with air particulate matter are presented directly to the XRF unit. Unless the filters are extremely loaded, no correction for X-ray absorption in the aerosol material is usually necessary.

The part of the filter with a sample actually analyzed by XRF has an area of only a few square centimeters and hence it must be representative for the entire sample. Therefore, a critical step is the selection of an appropriate filter material. Teflon\(^\circledR\) and polycarbonate (Nucleopore) filters are ideal because of their high purity and because they are surface collectors. Whatman-41 cellulose filters have been used widely because of their low cost, but they are rather thick (around 9 mg cm\(^{-2}\) versus 1.1 mg cm\(^{-2}\) for Nucleopore), which leads to more X-ray scatter and higher detection limits. They also partially collect particulate matter within their depth, so that X-ray absorption corrections become more complicated. Glass-fiber filters should be avoided in any case owing to their high inorganic impurity. High-purity quartz-fiber filters have recently been proposed. Before selecting a filter material for a particular application, the blank count of the filter or background level of the material to be analyzed must be determined because all filters contain various elements as major, minor and trace constituents.

Regarding aerosol analysis, several factors that affect X-ray intensity must be considered: attenuation of X-rays within the individual aerosol particle is only important for particles larger than a few micrometers, but accumulation of particles can have an effect (in the case of heavily loaded filters) and the filter itself can attenuate incident and emerging X-rays (if particles are not collected on the surface). An appropriate correction involves knowledge of the particle size distribution and selection of an adequate sampling time and an appropriate filter material. For example, if thin filters like Nucleopore or Millipore are selected for the collection, the absorption effects in the filter itself are small and often negligible for X-rays above 1 keV, because normally all particles should be retained at the filter surface. However, for light elements such as Si, P, S and Cl the absorption effect needs to be corrected by using a suitable correction procedure.

Besides conventional XRF, TXRF also nowadays is applied more frequently for aerosol analysis.\(^{23}\) To take advantage of the low detection limits and to reduce the matrix effects originating from the collection material, filter samples need to be digested. Normally, aerosol-loaded filters are dissolved with suprapure concentrated (70%) HNO\(_3\) and HF acids in a high-pressure digestion vessel. A standard is normally added prior to digestion. With this procedure, element concentrations of from 0.2 ng m\(^{-3}\) for Cu and 1 ng m\(^{-3}\) for Mn are easily determined.

8 STANDARDS

X-ray spectrometry is essentially a comparative method of analysis; therefore it is necessary that all standards and unknowns have a high degree of similarity (approximately the same matrix composition) and that they are presented to the spectrometer in a reproducible and identical way. Standards may be a Certified Reference Material or a sample itself, but analyzed by another analytical technique. Many specimens in use may also be prepared in the laboratory. They are usually composed of one or more elements at different levels of concentration within different matrices. For standards, it is essential to provide high count rates for the analyte element. Sometimes use is made of an internal standard. Standards can be liquid, gas or solid and can be pure, mixed powder, natural or synthetic materials.

Today, there are 3000 reference standards listed in catalogues and hundreds more in preparation. These standards include ores, metals and alloys, rocks, minerals, waste products and dusts collected by electrostatic precipitators. Environmental problems have increased the demand for standards for tailings, industrial wastes and isotopic materials.

Structure Determination, X-ray Diffraction for

D.D.L. Chung
State University of New York at Buffalo, Buffalo, USA

1 Introduction to X-ray Diffraction

1.1 Principles of Diffraction

X-rays are electromagnetic radiation with a wavelength of the order of 1 Å. Because of its inherent electric field, it interacts with charged particles, such as electrons in a solid. This interaction causes the electrons to emit wavelets. When these wavelets interfere with one another constructively, diffraction takes place.

Two criteria must be satisfied in order for constructive interference to occur. One criterion for constructive interference is given by Bragg’s law (Equation 1):

\[ \lambda = 2d \sin \theta \] (1)

where \( \lambda \) is the wavelength of the X-ray, \( d \) is the spacing between planes of atoms in the solid, and \( \theta \) is the angle of incidence, as illustrated in Figure 1.

The second criterion for constructive interference is that the arrangement of atoms in the unit cell of the solid under examination allows constructive interference to occur for that particular set of planes with interplanar spacing \( d \). The allowed planes for constructive interference are those for which the structure factor is not zero. For example, for a face-centered cubic (fcc) crystal structure, the structure factor is not zero when the Miller indices \( h, k, l \) of the planes are either all even or all odd, so that the allowed planes for constructive interference have Miller indices 111, 200, 220, etc. In contrast, for a body-centered cubic (bcc) structure, the structure factor is not zero when \( h + k + l = \) an even integer, so that the allowed planes for constructive interference have Miller indices 110, 200, 211, 220, etc. Thus, the systematic absence of diffraction from certain planes provides a signature for identifying the atom arrangement in the unit cell.

The \( \theta \) angle at which diffraction occurs (together with Equation 1) provides a determination of the interplanar
Angles while the diffracted intensity at a fixed angle is measured as a function of the rotation and tilt angles. A complete diffraction pattern. For a single-crystal sample, all the diffracted beams need to be detected in order to obtain the complete diffraction pattern. For a single-crystal sample, the sample must be oriented appropriately in order to make a certain crystallographic plane be capable of causing diffraction. Thus, the single-crystal sample must be oriented differently to cause diffraction to occur from a differently oriented crystallographic plane.

The X-ray incident on the sample is ideally monochromatic. For that purpose, the beam to be monochromatized is incident on a monochromator. A monochromator is either a single crystal or a highly oriented polycrystalline material, which allows a diffracted beam at a well-defined monochromatic wavelength to emanate from it according to Bragg’s law (Equation 1). For less stringent monochromatization, a filter is used; the filter is a material that preferentially absorbs radiation of wavelength below

1.2 Instrumentation for X-ray Diffraction

The instrumentation for X-ray diffraction involves an X-ray source, which provides the incident beam on the sample, and an X-ray detector, which measures the intensity of the diffracted beam emanating from the sample at a certain angle.

For a polycrystalline or powder sample, different crystallographic planes may be oriented simultaneously at their corresponding Bragg angle (θ) with respect to the incident beam, so that they may cause diffraction to occur simultaneously at different angles (2θ, the diffraction angle) from the incident beam. Thus, a number of diffracted beams may emanate from the same sample at the same time. All these diffracted beams need to be detected in order to obtain the complete diffraction pattern. For a single-crystal sample, the sample must be oriented appropriately in order to make a certain crystallographic plane be capable of causing diffraction. Thus, the single-crystal sample must be oriented differently to cause diffraction to occur from a differently oriented crystallographic plane.
STRUCTURE DETERMINATION, X-RAY DIFFRACTION FOR

a certain value, which is called the absorption edge, in order to remove the Kβ radiation.

The X-ray source generates X-rays (called the bremsstrahlung) by the deceleration (upon hitting a target or being deflected by a magnet) of electrons traveling with a kinetic energy determined by the acceleration voltage encountered by the electrons. The higher the kinetic energy of the electrons, the higher the intensity of the bremsstrahlung. In addition, X-rays (called characteristic X-rays) are generated when the target of the electrons undergoes electronic transition due to excitation of the target atom. The bremsstrahlung has a continuous range of wavelengths (called the continuous spectrum); characteristic X-rays have wavelengths characteristic of the element (e.g., Cu) in the target (called the characteristic spectrum). In addition to generating X-rays, heat is generated in the bombarded target, which therefore must be cooled. If the electrons do not hit the same spot in the target all the time, the chance of melting the target is diminished and electrons of a higher current density can be tolerated. This is the idea behind the rotating-anode (target) X-ray source, which provides higher-intensity X-rays than the sealed-tube (stationary anode) X-ray source. Because electrons must travel in a vacuum, the target must be housed in a vacuum, which can be maintained in a sealed tube (possible for a stationary anode) or by continuous evacuation (necessary for a rotating anode). Electrons of extremely high kinetic energy are available in an accelerator such as a synchrotron (i.e., a storage ring). The bending of the electron beam in a synchrotron by using magnets can cause extremely intense X-rays (continuous spectrum) to be generated. Therefore, sealed tubes, rotating anodes, and synchrotron radiation are three kinds of X-ray sources, listed in order of increasing X-ray intensity.

The X-ray detector can be either a scintillation (or similar) counter or a position-sensitive detector, so that the detector must be moved in order to detect X-rays emanating from the sample at a different angle. This movement makes simultaneous detection of various diffracted beams impossible, thus making the collection of the full diffraction pattern time-consuming. In contrast, the latter detects and differentiates among the X-ray beams hitting different spots (along a line or in a two-dimensional array) in the detector, so that diffracted beams emanating from the sample at different angles can be detected simultaneously and the diffraction pattern can be collected quickly.

1.3 Applications of X-ray Diffraction

X-ray diffraction using a (more or less) monochromatic X-ray beam incident on a polycrystalline or powder sample is the most widely used configuration. The resulting diffraction pattern (i.e., diffracted intensity vs. 2θ) can be used for phase identification, although only crystalline phases can be identified. Both the 2θ positions and the relative peak intensities are used to help the phase identification. At least the strongest peaks of the suspected phase must be observed with about the expected intensity ratios in order for the phase identification to be certain. (A common pitfall is to claim that a certain phase has been identified on the basis of one or two peaks.) Coexisting phases in the same sample can be identified from the same diffraction pattern, provided that each phase is associated with a sufficient number of peaks at the expected intensity ratios. From the relative integrated intensities of the peaks due to different phases, the relative amounts of the phases can be estimated qualitatively. From the relative intensities of the peaks associated with different crystallographic planes of the same phase, the preferred orientation (texture) of the phase can be estimated qualitatively. From the fwhm of a peak, the grain size (for a polycrystalline sample) or the particle size (for a powder sample) can be estimated from the Scherrer equation for grain or particle sizes less than about 1000 Å.

For a quantitative determination of the concentration of a certain phase in a sample, the use of standards in the form of materials containing the same phases at known concentrations and with similar textures is necessary. Any difference in thickness between the sample and the standard can be corrected for by using $G_x = 1 - e^{-2\mu x \sin \delta}$ (for a diffractometer), where $G_x$ is the fraction of the total integrated diffracted intensity contributed by a surface layer of depth x, $\mu$ is the linear absorption coefficient (product of the mass absorption coefficient and the density), and $\delta$ is the Bragg angle.

For a quantitative determination of the texture, pole figure determination is necessary. Figure 2 illustrates the Schulz reflection method, which is one of the most widely used methods. In this method, at a fixed 2θ angle, the sample is rotated about the AA' axis (angle $\alpha = 0 \rightarrow 90^\circ$) and also the BB' axis normal to the sample surface (angle $\delta = 0 \rightarrow 360^\circ$). The result of diffracted intensity (at a fixed 2θ angle) versus $\alpha$ and $\delta$ is conventionally displayed in a circle (called the Wulff net) with $\delta$ varying from 0° to 360° along the circumference and $\alpha$ varying from 0° to 90° along a radius from the circumference to the center of the circle (Figure 3). The intensity can be shown as contours in the circle, thereby indicating the sample orientations (the combinations of $\alpha$ and $\delta$) that give a diffracted intensity of a certain level for the fixed 2θ angle. The smaller the width of a “mountain” depicted by the contours, the greater the degree of texturing for the texture component corresponding to that mountain. The higher the mountain, the greater the strength of that texture.
component. Different mountains can belong to the same texture component (owing to symmetry) or to different texture components of the same phase. By changing \(2\theta\) to a different value of the same phase, additional clues can be obtained to ascertain the correctness of the texture determination. By changing \(2\theta\) to a value associated with a different phase, the texture of the other phase can be determined similarly. The preferred orientation relationship of coexisting phases can be determined by superimposing the pole figures of the different phases.

The lattice parameter (lattice constant) of a phase can be changed by solid solution formation or strain. For precise lattice parameter measurements, diffraction peaks with \(2\theta\) as near to 180° as possible should be used. This is because differentiation of Bragg’s law with respect to \(\theta\) gives \(\Delta d/d = -\cot \theta \Delta \theta\).

In the case of a sample with a cubic unit cell of dimension \(a\), Equation (2) is applicable and gives \(\Delta a/a = \Delta d/d\). Therefore, \(\Delta a/a = -\cot \theta \Delta \theta\). Because \(\cot \theta\) approaches zero as \(\theta\) approaches 90° (or \(2\theta\) approaches 180°), \(\Delta a/a\) (the fractional error in \(a\) caused by a given error in \(\theta\)) also approaches zero when \(\theta\) approaches 90°.

2 SYMMETRY

2.1 The Crystal Lattice and Net Planes

A crystal with all its atoms is represented by its unit cell. The whole crystal can be constructed by placing one cell beside or beneath another. This procedure (i.e. shifting and copying the unit cell) is called translation. The translation vectors are shown in Equation (8):

\[
t_m = m_1 \mathbf{a} + m_2 \mathbf{b} + m_3 \mathbf{c}
\]  

where \(\mathbf{a}\), \(\mathbf{b}\) and \(\mathbf{c}\) are the basis vectors of the unit cell and \(m_1\), \(m_2\), and \(m_3\) are integers.

The vertices of all these cells are lattice points of the crystal. Each lattice point is symmetrically equivalent; from the point of view of symmetry, all lattice points have an identical environment. Through these points one can construct parallel planes, called the net planes. The different orientations of these planes with respect to the unit cell are indicated by the Miller indices \(h, k, \) and \(l\). Net planes form the surface of a well-grown crystal. A lattice plane intersects the axes of the coordinate system. If the distance from the origin to the intersecting points is \(a_1\) for the \(a\)-axis, \(a_2\) for the \(b\)-axis, and \(a_3\) for the \(c\)-axis, then the Miller indices are obtained according to Equation (9):

\[
(h, k, l) = N \left( \frac{1}{a_1}, \frac{1}{a_2}, \frac{1}{a_3} \right)
\]  

where \(N\) is the smallest common factor such that the indices \(hkl\) become integers. Owing to the periodicity of the translation, the plane with the indices \(hkl\) consists of a set of equidistant parallel planes at the distance \(d\). The multiples of \(hkl\), say \(mhkl\), \(mk\), and \(ml\) give a set of parallel planes at the distance \(d/m\). The Miller indices of a plane or a set of planes are written in parentheses as \((hkl)\); the set of symmetrically equivalent planes are written in braces as \([h, k, l]\). For example, the front face of a cube is denoted by \((100)\); the six faces \((100), (010), (001), (100), (010), \) and \((001)\) are combined in one symbol \([100]\).
Lattice vectors are also used to indicate directions, which are written in brackets as \([uvw]\). For example, the positive directions parallel to the axes \(a\), \(b\), and \(c\) are \([100]\), \([010]\), and \([001]\), respectively. The set of symmetrically equivalent directions to \([uvw]\) is given by \((uvw)\).

According to the directions of symmetry of the crystal, an appropriate unit cell is chosen. The unit cells of the seven crystal systems are listed in Table 1.

2.2 Symmetry of Point Groups

In this section, a short introduction to the symmetry of crystals is given. To gain a deeper insight, other textbooks should be considered.\(^{(1\text{--}13)}\)

Let us look at a cube in a certain direction normal to one of its faces (Figure 4a). The origin of the coordinate system is placed at the body center of the cube. The \(a\)-axis is pointing at you, the \(b\)-axis to the right-hand side, and the \(c\)-axis upward. A rotation of 90° around the \(a\)-axis maps the cube onto itself. After four rotations of 90°, the cube is in its initial position. This symmetry

Figure 5 Rotoinversion: rotation axis along [001] and inversion center at the origin, i.e. 1, 3, 4, and 6.
The symmetry of a crystal with a cube as unit cell is characterized by a threefold inversion axis, 3, also containing a center of inversion, 1. The following combinations of symmetry elements also contain a center of inversion: 2/m, 4/m, 6/m. Consider a cube as a representation of a cubic crystal. First, look along the direction of a vector with the components 1, 0, 0. Such a direction has the symbol [100]. Normal to this direction, in the middle of the cube, is a mirror plane. This maps the front of the cube to the back, and vice versa. A mirror plane has the symbol m. The orientation of a plane is uniquely described by its normal direction. The symmetry of the cube with respect to the direction [100] is a fourfold rotation axis; normal to it is a mirror plane. The two symbols are combined to give 4/m.

Second, look along the direction of the body diagonal. As was mentioned earlier, this direction has the symbol [111]. It is a threefold rotoinversion axis, 3.

Third, look along the direction [110], onto the edge. We can rotate the cube by 180°. This is a twofold rotation axis with the symbol 2. Normal to it is a mirror plane m. The combination of the two symbols 2 and m is written as 2/m.

With these three directions, [100], [111], and [110], all symmetry elements of the cube are described. In the direction [100], normal to a face, we have 4/m; in the direction [111], a body diagonal, we have 3; in the direction [110], a plane diagonal, we have 2/m. Thus, the symbol 4/m 3 2/m describes the symmetry of the cube totally. The complete symmetry of the cube is exhibited by a cubic holohedron.

The symmetry of a crystal with a cube as unit cell can be lower. The four threefold axes along the body diagonals make the three coordinate axes a, b, and c equivalent. Thus, these axes create the cubic coordinate system. In other words, a symbol of a crystal class with the symmetry element 3 or 3 in the second position of the symbol belongs to the cubic crystal system. The cubic crystal classes are: 4/m 3 2/m, 4 3 2, 2/m 3, 4 3 m, 23. The cubic holohedron can be reduced so that in [100] only a twofold rotation axis and in [111] only a threefold rotation axis persists, whereas in [110] no symmetry element is retained. The symmetry is still compatible with the cubic unit cell (i.e. 23 in the notation just described). The four threefold axes of the body diagonals make the axes, a, b, and c of the unit cell equivalent.

Let us treat a tetragonal column with a square as the base plane (Figure 4c). This is a face form of a tetragonal crystal. We introduce the following coordinate system: a-axis normal to the rectangular face you are looking at, b-axis normal to the face at the right-hand side, and c-axis normal to the square face on top of the column. First, look along the direction [001], on top of the column. Here we have a fourfold axis and, normal to it, a mirror plane: 4/m. Second, look along the direction [100], onto the rectangular face. Here we have a twofold axis and normal to it a mirror plane: 2/m. The third direction is the bisector of the angle between the normals of the rectangular faces, i.e. the direction [110]. Here we find also the symmetry 2/m. Thus, the holohedral tetragonal system is described by the symbol 4/m 2/m 2/m.

The symmetry of the tetragonal holohedron can be reduced and the following point groups occur: 4 2, 4 m, 4 2 m, 4/m, 4. A crystal containing only one fourfold axis in [001] is tetragonal. The same procedure is applied to a hexagonal column with a hexagon as the base plane (Figure 4b). We look in a direction normal to a rectangular face of the column. The coordinate system is chosen as follows: the a- and b-axes lie in the hexagonal plane passing through the midpoint of the column. The a-axis points from the midpoint to the left edge of the front face of the column. The b-axis points at an angle of 120° from the a-axis toward the right side. The c-axis points upward normal to the hexagonal base plane.

To describe the symmetry, first look along the c-axis. This is the direction [001]. We find a sixfold rotation axis and a mirror plane normal to it: 6/m. The second direction is along the a-axis, i.e. [100], and we find 2/m. The third direction is normal to the rectangular front face, i.e. [210], and we find the symmetry 2/m. Thus, the total symmetry of the hexagonal column is 6/m 2/m 2/m, which is the symmetry of the hexagonal holoedrie. However, the smallest unit cell in the hexagonal system is not a hexagonal column. It is only one-third of the column, a section of 120° between the a-axis and the b-axis and parallel to the c-axis. The symmetry in the hexagonal system may be reduced to the following point groups: 6 2 2, 6 m m, 6 2 m, 6, 6m, 6, 3 2/m, 32, 3 2 m, 3.

A crystal containing only one threefold axis in [001] belongs either to the hexagonal system or to the rhombohedral system: An orthorhombic object is like a matchbox (Figure 4d). The coordinate axes are chosen normal to the faces, forming a right-handed, orthogonal coordinate system. Looking normal to the three faces in the directions [100], [010], and [001], we find in each case the symmetry 2/m 2/m 2/m, the holoedrie of the orthorhombic system. There are also the point groups 2 2 2 and 2 2 m.
A monoclinic object is like a sheared matchbox (Figure 4c). Using an undeformed matchbox with the coordinate system defined previously, a shear force in the direction of the \( b \)-axis is applied to the face normal to the \( a \)-axis on the back side, and a shear force with the direction \( b \) is applied to the face at the front. Upon the shear deformation, the top and the bottom faces become parallelograms, whereas the other faces remain rectangular. Thus, the symmetry of the orthorhombic object in the direction \([001]\) is retained as \( 2/m \), whereas in the other two directions the symmetry is lost. If the symbol \( 1 \) denotes a direction in which a symmetry element is no longer found, the symbol of the orthorhombic holohedron is reduced to \( 1 1 2/m \). Here the symmetry of the \( c \)-axis is retained; the \( c \)-axis is unique. It is customary to interchange the labels \( a, b, \) and \( c \) of the axes, so that the \( b \)-axis retains the symmetry \( 2/m \). This procedure leads to the symbol \( 12/m 1 \) as the symbol for the monoclinic holohedron with the \( b \)-axis unique. The monoclinic system contains also the point groups \( 2, m \). In the triclinic system the holohedron consists of the center of interversion, \( 1 \). Each face has a counterpart face related by the inversion. This symmetry can be reduced to the element \( 1 \), i.e. no symmetry along any direction.

A rhombohedron is a cube elongated or compressed in the direction \([111]\) (Figure 4f). This deformation changes the angles of the cube uniformly. The lengths of the base vectors \( a, b, \) and \( c \) are unchanged. By the deformation, the symmetries of the cube in the direction \([100]\) vanish, whereas those in the directions \([110], [101], \) and \([011]\) remain. From the symbol of the cubic holohedron \( 4/m \overline{3} 2/m \), which represents the symmetry in the cubic directions \([100], [111], \) and \([110]\), the first position is canceled and the second and third positions of the cubic symbol are retained. As in the tetragonal and hexagonal cases, the main axis \([111]\) (the threefold rotoinversion axis) is the first element in the symbol, followed by the symmetries normal to the main axis in the direction \([110]\). Thus, the symmetry of the rhombohedron is symbolized by \( \overline{3} 2/m \), the holohedral symmetry of the rhombohedral system. In the rhombohedral cell, the symmetry can be reduced to \( 32, 3m, 3, 3 \). We have already found these point groups among those of the hexagonal system. As is shown in the next section, the rhombohedral unit cell can be represented by a centered hexagonal unit cell. The hexagonal coordinate system is more comfortable than the rhombohedral coordinate system, so the hexagonal coordinate system is usually preferred for the representation of a rhombohedral crystal.

However, there are several difficulties in choosing the proper transformation between the two coordinate systems. The International Tables\(^\text{14}\) should be consulted carefully.

The 32 combinations of symmetry elements are crystallographic point groups. The midpoints of the bodies are left invariant by the symmetry. The 32 symmetry groups are also called crystal classes. Every crystal (or space group) belongs to only one crystal class (or point group). All crystal classes can be derived from the cubic or hexagonal holohedra as subgroups. The group–subgroup relations are shown in Figure 6. They are important to compare structures and to discuss phase transitions.

The symmetry of the macroscopic properties of a crystal obeys the symmetry of the point group of the crystal; the dielectric constants, the piezoelectric constants, the elastic constants, etc. are examples of macroscopic properties.

### 2.3 Space Groups

The point groups describe the symmetry of the crystal form and the physical properties of large well-grown crystals, but not their internal structure; this is performed by the 230 space groups. By the translation operation (Equation 8), space is filled by a replica of the unit cell. The macroscopic symmetry of a crystal is the result of the symmetry in the unit cell. The symmetry elements of a space group are isomorphic to those of the corresponding point group, i.e. in addition to mirror planes and rotation axes, glide planes and screw axes also occur.

#### 2.3.1 Lattice Types

The directions of the symmetry elements of the point groups (i.e. rotation axes and rotoinversion axes) have been defined earlier. The conventional unit cell is chosen in accordance with these directions. As a consequence, lattice types (the Bravais lattices) were introduced. In addition to the primitive lattice (denoted by the symbol \( P \)), centered lattices are also used. The \( P \) lattice has lattice points at the eight corners of the unit cell, i.e. only one lattice point per cell. These points are defined by translation, as introduced by Equation (11). In a centered lattice the volume of the unit cell is enlarged and additional translations (or shift vectors) are needed. These are given in Table 4 and are shown in Figure 7. In the rhombohedral system the lattice is denoted by \( R \) in order to distinguish this primitive unit cell from that of the hexagonal system. However, the rhombohedral lattice can also be described by a centered hexagonal unit cell, \( R_{\text{hex}} \). This cell is more
Figure 6 Subgroup relations between the 32 crystallographic point groups. In the left-hand part of the figure is listed the order of the group, i.e. the number of symmetry operations. This is also the number of symmetrically equivalent faces of the general face form with the indices \( hkl \). Straight lines give the normal subgroup relations; dashed lines give the conjugated subgroup relations.

2.3.2 Position of an Atom

The basis vectors of the unit cell, \( \mathbf{a} \), \( \mathbf{b} \), and \( \mathbf{c} \), are used to indicate the position of an atom in the unit cell. The coordinates of an atom are given by \( x \), \( y \), and \( z \), so that the position vector emanating from the origin of the unit cell is given by Equation (10):

\[
\mathbf{r} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c}
\]  

2.3.3 Symmetry Operations

If we have a mirror plane normal to the basis vector \( \mathbf{a} \) through the origin of the unit cell, corresponding to

</table>

\[ \mathbf{a}, \mathbf{b}, \mathbf{c} / \mathbf{x}, \mathbf{y}, \mathbf{z} \]

\[ \mathbf{r} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c} = (x, y, z) \]

\[ \mathbf{r'} = x'\mathbf{a} + y'\mathbf{b} + z'\mathbf{c} = (x', y', z') \]

\[ \mathbf{r'} = \mathbf{W}\mathbf{r} \]

\[ \mathbf{W} = \begin{pmatrix}
W_{11} & W_{12} & W_{13} \\
W_{21} & W_{22} & W_{23} \\
W_{31} & W_{32} & W_{33}
\end{pmatrix} \]

\[ \begin{pmatrix} x \\ y \\ z \end{pmatrix} \]

Each atom at \( x, y, z \) and \( x', y', z' \) is symmetrically equivalent to another atom at \( -x, y, z \) and \( x, -y, z \), respectively. The transformation of coordinates is easily performed by matrices. Equation (10) can thus be written in matrix notation according to Equation (11):

A symmetrically equivalent position \( x', y', z' \) is also given by Equation (11), leading to Equation (12):

\[ \mathbf{r'} = \mathbf{W}\mathbf{r} \]

\[ \mathbf{W} = \begin{pmatrix}
W_{11} & W_{12} & W_{13} \\
W_{21} & W_{22} & W_{23} \\
W_{31} & W_{32} & W_{33}
\end{pmatrix} \]

\[ \begin{pmatrix} x \\ y \\ z \end{pmatrix} \]

Figure 7 The lattice types. **First row:** the side-face-centered lattice (\( S \); depending on the choice of the coordinate axes, the lattice type is called \( A, B, \) or \( C \)). **Second row:** the primitive lattice (\( P \)), the body-centered lattice (\( I \)), the all-face-centered lattice (\( F \)), and the centered hexagonal cell (\( R_{hex} \)). The primitive rhombohedral cell (\( R \)) is usually described by a centered hexagonal cell (\( R_{hex} \)).
where $W$ is the matrix of a point group symmetry operation, i.e. the matrix of a rotation or rotoinversion. As an example, the rotation by $+90^\circ$ around the $c$-axis, indicated by the symbol $4^+$, is given by:

$$
\begin{pmatrix}
0 & -1 & 0 \\
1 & 0 & 0 \\
0 & 0 & 1
\end{pmatrix}
$$

Insertion into Equation (12) gives the coordinates as described previously.

### 2.3.4 Symmetry of Space Groups

The symmetry operations of point groups return, after a number of operations, back to the starting position. In space groups, however, each lattice point is, with respect to symmetry, equivalent. Thus, after a number of operations, either the starting point or a point shifted by a translation from the starting point is reached. The symmetry operations of point groups return, after a number of operations, back to the starting position. In space groups, however, each lattice point is, with respect to symmetry, equivalent. Thus, after a number of operations, back to the starting position.

For a glide plane, the atom mapped behind the mirror plane is shifted in a direction parallel to the plane. For example, we consider the operation $4_1^+$. This is a rotation by $+90^\circ$, as was mentioned previously, followed by a shift of a quarter of the unit cell dimension along the $c$-axis. Thus, for this example, we get:

$$
\mathbf{r}' = (a, b, c) \begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \frac{1}{4} \end{pmatrix} = \begin{pmatrix} x \\ y \\ z + \frac{1}{4} \end{pmatrix}
$$

A symmetry operation may transform the atom at position $x, y, z$ onto a point outside the unit cell. By a translation, this point can be transformed back into the unit cell. Mathematically, the positions, $x', y', z'$ are computed with mod 1, i.e. all coordinates $x', y', z'$ are reduced to the range $0 < x, y, z < 1$.

### 2.3.5 General and Special Positions

The set of all symmetry operations $(W, w)$ of the space group transforms the position $x, y, z$ of one atom to all symmetrically equivalent positions. This set of all positions is called the general position. However, if an atom lies on a mirror plane or a rotation axis, the symmetry operations of the symmetry elements map the position onto itself. The number of positions is reduced. This is called a special position and it has a point group
symmetry defined by the symmetry elements passing through the point.

The special positions are important in inorganic structures; they enable the positioning of complex chemical formulae units in the unit cell. For example, quartz (SiO$_2$) crystallizes in the space group $P\overline{3}121$ with three formula units in the cell. The six oxygen atoms are in general positions, i.e.:

$$x, y, z; \bar{y}, x-y, z+\frac{1}{2}; \bar{x}+y, \bar{z}, z+\frac{2}{3}; y, x, \bar{z};$$

and the three silicon atoms are on twofold axes, i.e. $x, 0, \frac{1}{2}; 0, x, \frac{2}{3}; \bar{x}, \bar{x}, 0$. However, in structures with organic molecules, screw axes and glide planes are preferred. About 30% of these compounds crystallize in the monoclinic space group 14 ($P1\overline{2}1/c1$).

2.3.6 Space Group Symbols

There are 230 space groups (i.e. the possible combination of symmetry elements to map the crystal onto itself). The translation is indicated by the symbol of the lattice type, followed by the symbol of the symmetry of the unit cell, i.e. a point group symbol, in which the symbols of the rotation axes and mirror planes can be replaced by those of screw axes and glide planes.

For example, the space group 227 ($F4_1/d\overline{3}2/m$) is the symmetry of the diamond structure. The lattice type is F. In [100] there is a screw axis 4, and normal to it a d glide; in [111] there is the rotoinversion axis $\bar{3}$; in [110] there is a twofold axis 2 with a mirror plane $m$ normal to it.

The space group 62 ($P2_1/n2_1/m2_1/a$) is discussed as a second example. It has a primitive lattice $P$. In the direction [100] there are twofold screw axes normal to $n$ glide planes; in [010] there are 2, screw axes normal to mirror planes $m$; in [001] there are 2, screw axes normal to $a$ glides. An orthorhombic space group can be symbolized by several symbols. By exchanging the axes $a$, $b$, $c$ by $b$, $c$, $a$, the space group symbol becomes $P2_1/m2_1/c2_1/n$, i.e. the direction of the glide vector of the former glide plane $a$ must always point in the direction of the $n$ glide, which is transformed to the direction $c$. Thus, a space group should be symbolized by its standard symbol, as given in the International Tables, where the space groups are all listed extensively, including drawings.
Figure 9 Mirror and glide planes. In the first row the projection is along [001] or the c-axis, in the second row the projection is along [100] or the a-axis, in the third row it is along [010] or the b-axis, and in the fourth row several examples are given: a d-glide plane normal to [100], which occurs only in F-centered lattices; in the tetragonal and cubic systems, normal to [110] mirror planes and c-glide planes; in I-centered lattices, also d-glide planes.

3 THEORY OF DIFFRACTION

X-rays interact with electrons. In the picture of classical electrodynamics, each electron oscillates, as it is agitated by the incoming wave, and emits a spherical wave. These waves interfere with the waves emitted by other electrons. In principle, the whole space is filled with emitted radiation. This can be seen in gases, liquids, and amorphous materials. Crystals, however, emit X-rays only in special directions. The reason for this effect is the crystal lattice and its condition of interference. Nonperiodic defects, inclusions of liquids, etc. in a crystal contribute to the diffuse background and can be analyzed if their concentration is high.

3.1 The Bragg Equation

The reflection of the X-rays by a crystal can be described as a reflection by its net planes (hkl). An incoming plane wave with the wavelength \( \lambda \) is reflected by a set of net planes when the path difference of the wave reflected by neighboring net planes is a period of the wave. From Figure 10 it can be derived that the diffraction angle \( \theta_{hkl} \) is given by Equation (14):

\[
2d_{hkl} \sin \theta_{hkl} = \lambda
\]

where \( d_{hkl} \) is the distance between the reflecting net planes.

3.2 The Reciprocal Lattice

The diffraction of X-rays can be interpreted as the conservation of the momentum of the incoming wave \( \mathbf{s}_{i} \) and that of the reflected wave \( \mathbf{s}_{f} \) (the momentum of a wave is \( h\mathbf{s} \), where \( h \) is Planck’s constant; \( h\mathbf{r}^{*} \) is the momentum transfer). Both vectors have the same
The neighboring net plane must be equal to the wavelength \( l \) magnitude (modulus) \( 1/\lambda \). The difference of the vectors is shown by Equation (15):

\[
s_f - s_i = r_{hkl}^* \tag{15}
\]

and, as shown by Equation (16):

\[
|r_{hkl}^*| = \frac{1}{d_{hkl}} \tag{16}
\]

The vector \( r_{hkl}^* \) is normal to the net plane \((hkl)\) (Figure 10). Equation (14) can be written as shown by Equation (17):

\[
2 \sin \theta_{hkl} \lambda = |r_{hkl}^*| \tag{17}
\]

For each set of net planes with the Miller indices \((hkl)\), a normal vector \( r_{hkl}^* \) is defined. The end-points of such vectors are reciprocal lattice points. The vectors \( r_{hkl}^* \) emanate from the origin and their physical dimension is the reciprocal length.

The reciprocal lattice is given by Equation (18):

\[
r_{hkl}^* = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* \tag{18}
\]

where \( \mathbf{a}^*, \mathbf{b}^*, \) and \( \mathbf{c}^* \) are the basis vectors of the reciprocal space. The collection of three integers \( h, k, l \) (the Miller indices) define a lattice point.

If \( \mathbf{a}, \mathbf{b}, \) and \( \mathbf{c} \) are the basis vectors of the unit cell of a crystal, the basis vectors in reciprocal space \( \mathbf{a}^*, \mathbf{b}^*, \) and \( \mathbf{c}^* \) are obtained by Equations (19) and (20):

\[
\begin{pmatrix}
\mathbf{a} \\
\mathbf{b} \\
\mathbf{c}
\end{pmatrix}
= \begin{pmatrix}
\mathbf{a} \cdot \mathbf{a}^* & \mathbf{a} \cdot \mathbf{b}^* & \mathbf{a} \cdot \mathbf{c}^* \\
\mathbf{b} \cdot \mathbf{a}^* & \mathbf{b} \cdot \mathbf{b}^* & \mathbf{b} \cdot \mathbf{c}^* \\
\mathbf{c} \cdot \mathbf{a}^* & \mathbf{c} \cdot \mathbf{b}^* & \mathbf{c} \cdot \mathbf{c}^*
\end{pmatrix}
\begin{pmatrix}
\mathbf{a} \\
\mathbf{b} \\
\mathbf{c}
\end{pmatrix}
= \begin{pmatrix} a \\ b \\ c \end{pmatrix}
= \frac{1}{d_{hkl}} \tag{19}
\]

The vector \( \mathbf{a}^* \) is normal to the \( \mathbf{b} \)-\( \mathbf{c} \) plane, the vector \( \mathbf{a} \) is normal to the \( \mathbf{b}^* \)-\( \mathbf{c}^* \) plane, etc. (Figure 11). The lattice in direct space defines uniquely the lattice in reciprocal space, and vice versa. Thus, normal to a lattice translation \( \mathbf{t}_m \) in direct space is a set of net planes in reciprocal space at a distance \( d_{hkl}^* \). The choice of the unit cell in one space defines the unit cell in the other space. The volume of the reciprocal unit cell \( V^* \) is reciprocal to the volume of the unit cell in direct space, i.e. \( VV^* = 1 \). The rules for selection of the standard unit cells depend on the crystal system. If a choice does not agree with the rules, the unit cells in direct and reciprocal spaces should be transformed to the standard unit cells. This procedure is treated intensively in the International Tables.\(^{(14)}\)

The modulus of the vector \( r^* \) is given by Equations (21) and (22):

\[
|r_{hkl}^*|^2 = (h, k, l)
\begin{pmatrix}
\mathbf{a}^* \cdot \mathbf{a}^* & \mathbf{a}^* \cdot \mathbf{b}^* & \mathbf{a}^* \cdot \mathbf{c}^* \\
\mathbf{b}^* \cdot \mathbf{a}^* & \mathbf{b}^* \cdot \mathbf{b}^* & \mathbf{b}^* \cdot \mathbf{c}^* \\
\mathbf{c}^* \cdot \mathbf{a}^* & \mathbf{c}^* \cdot \mathbf{b}^* & \mathbf{c}^* \cdot \mathbf{c}^*
\end{pmatrix}
\begin{pmatrix} h \\ k \\ l \end{pmatrix}
= \frac{1}{d_{hkl}^2} \tag{21}
\]

\[
\begin{pmatrix}
\mathbf{a}^* \\
\mathbf{b}^* \\
\mathbf{c}^*
\end{pmatrix}
= \frac{1}{d_{hkl}} \tag{22}
\]

\textbf{Figure 10} The Bragg equation. The difference of the path of a ray reflected by a net plane \((hkl)\) with that reflected from the next neighboring net plane must be equal to the wavelength \( \lambda \) (i.e. \( 2d_{hkl} \sin \theta_{hkl} = \lambda \)).
Equation (24):
The modulus of a vector in direct space is given by

The formula is specified for the crystal systems in Table 7.

Equation (23):
and the metric tensor of reciprocal space is given by

Figure 11 The $hk0$ plane of a hexagonal lattice with the directions of the basis vectors $a^*$ and $b^*$ of reciprocal space. The origin is denoted by $O$. The directions of the basis vectors of direct space $a$ and $b$ are schematically indicated. The base vectors $c$ and $c'$ are normal to the $hk0$ plane.

and the metric tensor of reciprocal space is given by Equation (23):

\[
g^r = \begin{pmatrix}
a^* \cdot a^* & a^* \cdot b^* & a^* \cdot c^* \\
b^* \cdot a^* & b^* \cdot b^* & b^* \cdot c^* \\
c^* \cdot a^* & c^* \cdot b^* & c^* \cdot c^*
\end{pmatrix}
\] (23)

The formula is specified for the crystal systems in Table 7. The modulus of a vector in direct space is given by Equation (24):

\[
|\mathbf{r}|^2 = (x, y, z) \begin{pmatrix} a \cdot a & a \cdot b & a \cdot c \\ b \cdot a & b \cdot b & b \cdot c \\ c \cdot a & c \cdot b & c \cdot c \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}
\] (24)

and the metric tensor of direct space is given by Equation (25):

\[
g = \begin{pmatrix}
a \cdot a & a \cdot b & a \cdot c \\
b \cdot a & b \cdot b & b \cdot c \\
c \cdot a & c \cdot b & c \cdot c
\end{pmatrix}
\] (25)

The relations between the moduli of the basis vectors in direct space and reciprocal space are given in Table 8.

3.3 The Ewald Construction

The moduli of the incident and reflected waves $s_i$ and $s_f$ are both $1/\lambda$. Ewald made a geometric construction of Equation (15) in the reciprocal lattice. The reflection condition for a net plane $hkl$ is that the sphere of reflection with radius $1/\lambda$ passes the lattice point $hkl$ with the reciprocal lattice vector $\mathbf{r}_{hkl}^r$ (Figure 12). By the Ewald construction, reflection conditions for cameras and diffractometer are visualized. The reflection of a net plane can be shown by another type of drawing of the momenta (Figure 13). This representation is used to visualize the transfer of the divergence and the bandwidth of the incident beam to the reflected beam.

3.4 Symmetry in Reciprocal Space

In powder diffraction all reflections with equal $d_{hkl}$ (i.e. equal $|\mathbf{r}_{hkl}^r|$) superimpose. The crystal system and the lattice constants determine the values of $d_{hkl}$ and the positions of the powder reflections.

In the diffraction pattern of single crystals anomalous dispersion is not usually observed and Friedel’s law is valid, i.e. by the diffraction experiment a center of inversion is introduced into the diffraction pattern; the intensity $I(hkl)$ of the reflection $hkl$ is equal to $I(\overline{h\overline{k}\overline{l}})$. Noncentrosymmetric point groups have an additional center of inversion. Thus, only centrosymmetric classes, the 11 Laue classes, can be distinguished by inspecting the diffraction diagram of the single crystal (Table 9). In the case of anomalous dispersion (see section 3.5), Friedel’s law is no longer valid and the 32 point groups can be detected by their single-crystal diffraction pattern.

To a primitive lattice in direct space belongs a primitive lattice in reciprocal space. If, however, a centered unit cell is chosen, the cell in direct space is larger than a primitive unit cell, and in reciprocal space it is smaller than the corresponding primitive unit cell. Thus, centering in direct space produces systematic absences in reciprocal space. The reflection conditions are given also in Table 4. The condition $h + k + l = 2n$ for a body-centered lattice $I$ indicates that only reflections with the sum $h + k + l$ equal to an even number are present; the others are absent.

Glide planes give extinctions in reciprocal space. They can be seen in planes in reciprocal space. A glide plane normal to the $a$-axis, $b$-axis, or $c$-axis in direct space has extinctions in reciprocal space in the $0kl$ plane, $h0l$ plane, or $hkl$ plane respectively. For example, in the case of an $a$ glide normal to the $c$-axis there are only reflections with $h = 2n$ in the $hk0$ plane present. The reflection conditions can be found in Table 6.

Screw axes of direct space give extinctions on the axes in reciprocal space: a $4_i$ axis parallel to the $c$-axis produces $00l$ reflections, of which the reflections $l = 4n$ can be observed; the others with $l \neq 4n$ are extinct (see Table 5).

3.5 The Structure Factor

3.5.1 The Atomic Scattering Factor

The electrons of a single atom form a cloud around the nucleus. The incoming wave excites the electrons to

* It is convenient to use the centered hexagonal unit cell.
oscillations. In the direction of the incoming wave, all electrons oscillate in phase. However, with increasing scattering angle $\theta$, i.e. with larger distance $|\mathbf{r}'|$ from the origin of the reciprocal space, differences in the pathlength occur and the amplitude of the scattered wave is reduced. The atomic scattering factor $f_0(\sin \theta / \lambda) = f_0((\frac{1}{2})|\mathbf{r}'|)$. For $|\mathbf{r}'| = 0$, $f_0(0)$ is equal to the number of electrons in the atom. The function decreases rapidly and becomes almost constant at high values of $|\mathbf{r}'|$ angles (Figure 14).\(^{(15)}\)

If the frequency of the incident wave agitates an eigenfrequency of the atom, this simple picture must be modified. The scattering factor changes drastically at the wavelength near an absorption edge, anomalous dispersion occurs, and the scattering factor becomes a complex function. The real part must be corrected by $f'(\lambda)$ and an additional imaginary part $f''(\lambda)$ occurs owing to absorption. Thus, the atomic scattering factor is given by Equation (26):

$$f = f_0 \frac{1}{2} |\mathbf{r}'| + f'(\lambda) + i f''(\lambda)$$  \hspace{1cm} \text{(26)}

The atomic scattering factors are calculated by using quantum mechanics, assuming a free spherical atom. It should be noted that $f'(\lambda)$ can assume large negative values near the absorption edge. At a larger distance from the absorption edge, also small positive values of $f'(\lambda)$ occur. In many cases the distance from the absorption edge is so large that the contributions of $f'$ and $f''$ are neglected. From a synchrotron, radiation with each wavelength can be selected. The anomalous dispersion is now applied in many experiments.

Slight deviations from the model of free spherical atoms occur in solids. Bonding electrons and polarization of the electron clouds in the crystal field deform the spherical symmetry of the clouds of electrons. Thus, the function $f$ is also deformed. This was also detected for $f'$ and $f''$ in the case of anomalous dispersion by Templeton and Templeton\(^{(16)}\) (Figure 15).

The absorption of the X-rays at the absorption edge produces fluorescent radiation. The incident photon pushes out an electron and produces a photo effect, i.e. a hole in the K shell of the anomalously scattering atom. The hole is filled by an electron of an outer shell and fluorescent radiation is produced. This is similar to the production of the characteristic radiation in an X-ray tube. The incident photon must have a higher energy (or smaller wavelength) than that of the fluorescent radiation. This radiation can give a high contribution to the background, which can be avoided by the proper choice of anode material for the X-ray tube (e.g. an iron tube instead of a copper tube when a sample with iron or manganese is studied) or by placing an excellent monochromator in front of the detector.

Figure 12 The Ewald construction in a reciprocal lattice plane $hk0$: $s_i$ is the momentum of the incident beam, $s_f$ is the momentum of the reflected beam, and $r_{hk0}$ is the vector of the reciprocal lattice. A reflection is only possible if a lattice point $hk0$ with the lattice vector $r_{hk0}$ coincides with the sphere of reflection with the radius $1/\lambda$.

Figure 13 The momentum vectors of the incident beam $s_i$, the reflected beam $s_f$ and the normal vector $r_{hk0}$ of the net plane $hk0$ in a different representation.

</table>
The absorption edge has a fine structure that depends on the electronic state of the atom and the environment of the scattering atom. The analysis of this effect has become a new field of investigation, called extended X-ray absorption fine structure (EXAFS). The structure of the neighborhood of the anomalously scattering atom can be determined. This procedure is also applied in the case of amorphous materials or in samples in which the anomalous scatterer is an interstitial atom.

3.5.2 The Structure Factor

An incoming plane wave excites the electrons of the atoms, and each of the $N$ atoms in the unit cell is a source of a spherical wave. The sum of these waves is given by the structure factor as shown by Equation (27):

$$ F(hk) = \sum_{j=1}^{N} f_j \exp[2\pi i (hx_j + ky_j + lz_j)] $$  \hspace{1cm} (27)
where \( hkl \) are the Miller indices of the reflecting net plane, \( x_j, y_j, z_j \) are the positions, and \( f_j \) is the scattering factor (Equation 26) of the \( j \)th atom in the unit cell. The exponential function gives the phase differences of the scattered waves with respect to a wave scattered at the origin of the unit cell. The structure factor describes the fact that the reflections \( hkl \) differ in amplitude and phase. If both are known, the crystal structure can be calculated by a Fourier transform. From the usual diffraction experiments, only the moduli can be determined. The procedure of structure determination from the moduli is difficult. Complicated methods have been developed that are in most cases successful. There are many textbooks for further reading.\(^{17-30}\)

For the moment, only one type of atom in one general position in the unit cell is considered. If no anomalous dispersion occurs, the structure factor is given by Equations (28) and (29):

\[
F(hkl) = f_0 \sum_{j=1}^{N} \cos[2\pi(hx_j + ky_j + lz_j)] \\
+ if_0 \sum_{j=1}^{N} \sin[2\pi(hx_j + ky_j + lz_j)]
\]

(28)

\[
= f_0(A + iB)
\]

(29)

and \( A \) and \( B \) are given by Equations (30) and (31):

\[
A(hkl) = \sum_{j=1}^{N} \cos[2\pi(hx_j + ky_j + lz_j)]
\]

(30)

\[
B(hkl) = \sum_{j=1}^{N} \sin[2\pi(hx_j + ky_j + lz_j)]
\]

(31)

The square of the modulus \( F(hkl) \) is given by Equation (32):

\[
FF^* = f_0^2A^2 + f_0^2B^2
\]

(32)

For a crystal, all different atomic positions in the unit cell have to be included in the structure factor.

In the general case, \( F(hkl) \) is a complex number and its phase angle can assume any value. In the case of a centrosymmetric structure, when a center of inversion is situated at the origin, the formula is reduced. To each atom at \( x, y, z \), an equivalent one exists at \( \bar{x}, \bar{y}, \bar{z} \). Thus, \( B(hkl) = 0 \), and \( F(hkl) \) becomes a real function that has either a positive or a negative sign. In order to solve an acentric structure, the phases of the reflections \( F(hkl) \) have to be determined. In the centrosymmetric case the problem is less difficult; only the signs of the reflections have to be assigned to \( F(hkl) \).

### 3.5.3 The Temperature Factor

The atoms in a crystal are not at rest; they oscillate because they are excited by phonons. This is taken into account by the temperature factor. During the time of an experiment, the positions of the atoms are smeared out...
in first approximation by a spherical Gaussian function, which is written according to Equations (33) and (34):

\[ q(hkl) = \exp\{-B_j \sin^2 \theta \lambda^2 \} \]  

(33)

\[ q(hkl) = \exp[-B_j \frac{1}{2} \mathbf{r}^2] \]  

(34)

where \( B_j \) is the isotropic temperature factor of an atom with index \( j \). The physical interpretation of \( B_j \) is the mean square displacement (msd) of the atom in first approximation by a spherical Gaussian function, as shown in Equation (34). The tensor \( \mathbf{b} \) is transformed according to Equation (40):

\[ \mathbf{b}' = \mathbf{W} \mathbf{b} \mathbf{W}^T \]  

(40)

where \( \mathbf{W} \) is the transposed matrix of \( \mathbf{W} \), i.e. in components according to Equation (41):

\[ b''_{mn} = \sum_{m=1}^{3} \sum_{n=1}^{3} W_{mk} b_{kl} W_{nl} \]  

(41)

The mean square displacement (msd) of the atom is not isotropic. For each atom an ellipsoidal smearing function is introduced. The anisotropic motion is written according to Equation (36):

\[ q(hkl) = \exp(-b_{11} h^2 + b_{22} k^2 + b_{33} l^2 + 2 b_{23} kl + 2 b_{13} hl + 2 b_{12} hk) \]  

(36)

In matrix notation the exponent becomes that shown in Equation (37):

\[ -(h, k, l) \begin{pmatrix} b_{11} & b_{12} & b_{13} \\ b_{21} & b_{22} & b_{23} \\ b_{31} & b_{32} & b_{33} \end{pmatrix} \begin{pmatrix} h \\ k \\ l \end{pmatrix} = -(hkl) \mathbf{b} \begin{pmatrix} h \\ k \\ l \end{pmatrix} \]  

(37)

where \( \mathbf{b} \) is a symmetric tensor describing the anisotropic motion.

The mean square displacement (msd) of the atom in the direction of the vector \( \mathbf{m} \) in direct space is obtained by Equations (38) and (39):

\[ \text{msd}(\mathbf{m}) = \frac{1}{2\pi^2} \frac{m'B \mathbf{g} m}{m' \mathbf{g} m} \]  

(38)

\[ \times \begin{pmatrix} m_1 a & m_2 b & m_3 c \\ m_1 a & m_2 b & m_3 c \\ m_1 a & m_2 b & m_3 c \end{pmatrix} \begin{pmatrix} m_1 a & m_2 b & m_3 c \\ m_1 a & m_2 b & m_3 c \\ m_1 a & m_2 b & m_3 c \end{pmatrix} \]  

(39)

where \( \mathbf{g} \) is the metric tensor (Equation 26).

To interpret the results, the tensor has to be transformed to the main axes in a Cartesian coordinate system. There are excellent computer programs to take care of this and to draw the structure, including the ellipsoids of the anisotropic motion.

Like the positions of the atoms, the temperature factors also have to obey the symmetry of the crystal. If a symmetry operation \( (\mathbf{W}, \mathbf{w}) \) transforms the position of the atom at \( x, y, z \) to \( x', y', z' \) (Equation 13), the tensor of the anisotropic motion also has to be transformed accordingly. The transformation is performed only by the rotational part \( \mathbf{W} \) of the symmetry operation (see section 3.3). The tensor \( \mathbf{b} \) is transformed according to Equation (40):

\[ \mathbf{b}' = \mathbf{W} \mathbf{b} \mathbf{W}^T \]  

(40)

The anisotropic motion is described by an ellipsoid. It has to fulfill the point symmetry of the position of the atom. On a position with cubic symmetry, an ellipsoid degenerates to a sphere. If the atom is located on a three-, four-, or sixfold rotation axis, the ellipsoid must be rotationally symmetric with respect to this axis. An orthorhombic symmetry requires that the main axes of the ellipsoid coincide with the orthorhombic symmetry axes. On a point with monoclinic point symmetry, the ellipsoid has to be oriented parallel to the mirror plane, or with one axis parallel to the two fold rotation axis. On a general position or on a center of symmetry, there is no restriction to the orientation of the ellipsoid.

Thus, the complete structure factor is given by Equation (42):

\[ F(hkl) = \sum_{i=1}^{N} (f_0 + f' + if'') q_i(hkl) \times \exp[2\pi i(hx_j + ky_j + lz_j)] \]  

(42)

3.5.4 The Electron Density

The Fourier transform of all structure factors gives the electron density, \( \rho(X, Y, Z) \), of the unit cell. However, not only the moduli \( |F(hkl)| \) have to be known, but in an acentric structure their phases also: in a structure with an inversion center at the origin of the unit cell, the signs of \( F(hkl) \) have to be known too. Thus, according to Equation (43):

\[ \rho(X, Y, Z) = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F(hkl) \times \exp[-2\pi i(hX + kY + lZ)] \]  

(43)

where \( X, Y, Z \) are the components of a vector \( \mathbf{r} \) in the unit cell. By the inverse transformation, the structure factors can be computed from the electron density, as shown in
STRUCTURE DETERMINATION, X-RAY DIFFRACTION FOR

Equation (44):

\[ F(hkl) = \rho(X, Y, Z) \]
\[ \times \exp[2\pi i(hX + kY + lZ)] dX dY dZ \] (44)

Because \( \rho(X, Y, Z) \) is a continuous function in the unit cell, in the reverse transformation the sums are replaced by integrals. In the map of electron density, each atom is shown with its cloud of electrons smeared out by the temperature motion. Even bonding electrons between the atoms can be seen.

From the experiment, \(|F|^2\) is obtained. Its Fourier transform, called the Patterson function, can be calculated as shown by Equation (45):

\[ P(X, Y, Z) = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} |F(hkl)|^2 \]
\[ \times \exp[-2\pi i(hX + kY + lZ)] \] (45)

The Patterson function is the convolution of the electron density functions \( \rho(X, Y, Z) \) and \( \rho(-X, -Y, -Z) \), as shown in Equations (46) and (47):

\[ P(X, Y, Z) = \rho(X, Y, Z) \times \rho(-X, -Y, -Z) \]
\[ = \rho(u, v, w) \]
\[ \times \rho(u + X, v + Y, w + Z) \] du dv dw

(47)

The Patterson function has interesting properties. It is a periodic function that has the same unit cell as the crystal. Let us consider the atoms \( j \) and \( k \) in the unit cell, at the positions \( \mathbf{r}_j \) and \( \mathbf{r}_k \), which have the number of electrons \( n_j \) and \( n_k \), respectively; the difference of the position vectors is given by Equation (48):

\[ \Delta \mathbf{r}_{jk} = \mathbf{r}_j - \mathbf{r}_k \] (48)

At the position \( \Delta \mathbf{r}_{jk} = (\Delta X_{jk}, \Delta Y_{jk}, \Delta Z_{jk}) \) with \( j \neq k \), the Patterson function has a peak proportional to the product of the numbers of electrons, i.e. the convolution of the electron clouds of atoms \( j \) and \( k \), as shown by Equation (49):

\[ P(\Delta \mathbf{r}_{jk}) \sim n_j n_k \] (49)

An example is shown in Figure 16.\(^{32} \) From this function the pair correlation function can be derived, i.e. the number of atoms of kind \( k \) at the distance \( \Delta \mathbf{r}_{jk} \) from atom \( j \).

At the origin of the unit cell of the Patterson function, each electron cloud of an atom is convoluted with itself, and thus a peak is obtained that is the sum of the squares

\[ \rho(x) = \frac{c_1}{\sqrt{\pi b_1^2}} \exp \left( -\frac{x - a_1}{b_1} \right) + \frac{c_2}{\sqrt{\pi b_2^2}} \exp \left( -\frac{x - a_2}{b_2} \right) \]

(b) Convolution of the function \( \rho(x) \) with \( \rho(-x) \), according to Equation (47) (from Hosemann and Bagchi\(^{32} \)):

\[ \rho(x) \times \rho(-x) = \frac{c_1^2}{\pi b_1^2} \exp \left( -\frac{x^2}{2b_1^2} \right) + \frac{c_2^2}{\pi b_2^2} \exp \left( -\frac{x^2}{2b_2^2} \right) \]
\[ + \frac{c_1 c_2}{\pi (b_1^2 + b_2^2)} \exp \left( -\frac{(x \pm (a_1 - a_2))^2}{b_1^2 + b_2^2} \right) \]

of the electrons of all atoms in the unit cell, as shown by Equation (50):

\[ P(0) \sim \sum_{j=1}^{N} n_j^2 \] (50)

If only one kind of atom is in the unit cell, the self-correlation function can be obtained.

3.6 Intensity

The structure factors \( F(hkl) \) contain the information of the crystal structure. In order to obtain \(|F(hkl)|\), the measured intensities must be corrected for systematic errors owing to the physics of the diffraction. This section begins with a discussion of the correction functions.

3.6.1 The Lorentz Factor

In order to measure the integrated intensity, the reciprocal lattice point must be swept through the sphere of reflection. The rotation axis is usually normal to the reflection plane. All reciprocal lattice points have the
same angular velocity. However, the lattice points are not real points. They show the width of the mosaic distribution. The time in which the reflection sweeps through the Ewald lattice depends on the angle at which the reciprocal lattice point passes the surface of the sphere. This is corrected by the Lorentz factor, as in Equation (51):

$$L = \frac{1}{\sin 2\theta} \quad (51)$$

If the reflection plane is not normal to the rotation axis, the Lorentz factor must be modified.

### 3.6.2 The Polarization Factor

Neutrons have no polarization and their polarization factor is given by Equation (52):

$$P_n = 1 \quad (52)$$

X-rays, however, are electromagnetic waves that can be polarized. The plane of diffraction is defined by the vectors of propagation of the incoming beam $s_i$ and of the diffracted beam $s_f$. The component of the polarization vector of the incoming beam, which is normal to the diffraction plane $s_i, s_f$, transfers unchanged to the diffracted beam. The component of the polarization vector of the incoming beam, which is parallel to the plane $s_i, s_f$, contributes to the diffracted beam only by its projection, i.e., with the factor $\cos 2\theta$. If the diffracting crystal is of perfect quality and reflects dynamically, the polarization factor becomes that shown in Equation (57):

$$P_n = \frac{c_n + c_p \cos^2 2\theta}{c_n + c_p} \quad (57)$$

where $c_n$ is the counting rate of the counter normal to the diffraction plane and $c_p$ is that within the plane. The equation assumes that the sample diffracts at the Bragg angle $\theta$ as a mosaic crystal.

### 3.6.3 The Geometric Factor

There are different cameras and diffractometers in use. Usually, the length of the beam path does not depend on the Bragg angle. However, when the length between crystal and counter (or film) varies with the Bragg angle, it has to be taken into account by the geometric factor $G$. In the case of single crystals measured by a four-circle diffractometer, the beam path is independent of the Bragg angle $\theta$ and $G$ is given by Equation (58):

$$G = 1 \quad (58)$$

The function is more complicated in the case of the Guinier powder diffraction, equi-inclination, or precession method.

In the case of powder diffraction the powder should have no preferred orientation (if the texture is not to be investigated). The vectors normal to the reflecting net plane $hkl$ are distributed over a sphere in reciprocal space with the radius $1/d_{hkl} = |r^*|$. Only the intersection of this sphere with the sphere of reflection fulfills the reflection condition (Ewald construction). The reflected intensity of the total Debye–Scherrer cone varies with $\frac{1}{4} \cos \theta$, but only a small section of the cone is recorded, proportional to $1/2\pi r \sin 2\theta$. Thus, the geometric factor becomes that shown in Equation (59):

$$G_{DS} = \frac{\cos \theta}{4\pi r \sin 2\theta} \quad (59)$$

where $r$ is the distance between the sample and the detector.

### 3.6.4 Absorption Corrections

The intensity $I_0$ of an X-ray beam passing through a material is reduced by absorption, mainly by the photo effect. After a ray has passed through a sheet of thickness
t (more precisely, a path with length t), the intensity is reduced to that shown by Equation (60):

$$I = I_0A_L$$  \hspace{1cm} (60)

and the linear transmission factor $A_L$ is given by Equation (61):

$$A_L = \exp(-\mu t)$$  \hspace{1cm} (61)

where $\mu$ is the linear absorption coefficient. In the case of a Bragg–Brentano diffractometer, the transmission factor becomes that expressed in Equation (62):

$$A_{BB} = \frac{1}{2\mu}$$  \hspace{1cm} (62)

This correction is important in the case of quantitative analysis of the composition of powders.\(^{(33)}\)

The correction of absorption becomes tedious for strongly absorbing single crystals or cylindrical samples in the Debye–Scherrer case. There are sophisticated computer programs that calculate the absorption factor numerically by integrating the possible beam paths.\(^{(34)}\)

Usually small samples are used, to avoid an absorption correction.

The linear absorption coefficient $\mu$ can be calculated from the chemical composition of the sample by using the mass absorption coefficients ($\mu_i/\rho_i$) of the chemical element $i$, according to Equation (63):

$$\frac{\mu}{\rho} = \sum_i a_i \frac{\mu_i}{\rho_i}$$  \hspace{1cm} (63)

where $\rho$ is the density of the sample and $a_i$ is the weight fraction of element $i$ in the sample.

### 3.6.5 The Lattice Factor

The structure factor takes only the contents of a unit cell into account. The diffracted beams of all unit cells in the crystal add with equal phase. Let us assume a crystal with $M_a$ unit cells in the direction of the lattice constant $a$. The unit cells are labeled by $m$, such that $0 < m < M_a - 1$. Each unit cell contributes to the diffracted beam with a phase factor $\exp(2\pi i mh)$. The sum over all unit cells is a geometric progression, as shown by Equation (64):

$$\sum_{m=0}^{M_a-1} \exp(2\pi i mh) = \frac{1 - \exp(2\pi i M_a h)}{1 - \exp(2\pi i h)} = \frac{\sin \pi M_a h}{\sin \pi h} \exp[\pi i (M_a - 1) h]$$  \hspace{1cm} (64)

The lattice factor (Equation 65) is the square of the modulus of this function in three dimensions, i.e.:

$$|H|^2 = \frac{\sin^2 \pi M_a h}{\sin^2 \pi h} \cdot \frac{\sin^2 \pi M_b k}{\sin^2 \pi k} \cdot \frac{\sin^2 \pi M_c l}{\sin^2 \pi l}$$  \hspace{1cm} (65)

where $h$, $k$, and $l$ are the Miller indices (i.e. the components of a lattice vector in reciprocal space) and $M_a$, $M_b$, and $M_c$ are the numbers of unit cells in the direction of the lattice constants $a$, $b$, and $c$. These numbers are usually very large. Thus, $|H|^2$ is essentially zero in reciprocal space and $N^2 = M_a M_b M_c$ at the position of a lattice point $hkl$; $N$ is the number of unit cells in the crystal.

With small $M$ values, the function $H$ becomes a broad maximum. This can be used to determine the particle size by using the Scherrer equation (Equation 6).

### 3.6.6 The Multiplicity Factor

In powder diffraction all net planes with an equal value of $1/d_{hkl}$ contribute to the same powder line. The number of contributing reflections is determined by the crystal system and the Miller indices $hkl$ of the reflecting net planes. The factor $M$ is given by the number of symmetrically equivalent net planes $hkl$ contributing to the reflection $hkl$. For example, $M = 6$ reflections contribute to a cubic powder line $h00$ according to the six faces $[100]$ of the cube; $M = 48$ reflections contribute to a reflection $hkl$ of the cubic holoedrie.

### 3.6.7 The Formula for the Intensity

The intensity is measured by sweeping the reciprocal lattice point $hkl$ through the sphere of reflection and integrating the reflected radiation during the motion. This value, corrected for the overall background, is the integrated intensity, or, in short, the intensity. It is denoted by $I(hkl)$.

The interference of waves is responsible for diffraction. The amplitudes of the waves add in accordance with the phases. Thus, the diffracted intensity is proportional to $|F(hkl)|$, the amplitude of the waves. This is valid for perfectly grown crystals, such as silicon used in electronics. This is called dynamic theory, because it takes into account all the interactions of the waves in the perfect crystal.

The conditions for this effect are very sensitive. Crystals that were grown fast contain a great number of slight deformations of the crystal lattice, produced by defects such as dislocations and faults. They disturb the interference of the waves. Small regions in the crystal diffract independently of their environment. The small regions act like the stones of a mosaic. In this case, it is assumed that each individual mosaic block is slightly misoriented and interacts with an unweakened ray of the source. This is the kinematic theory. The intensity is proportional to the square of the modulus of $F(hkl)$, i.e. $FF^*$. Unfortunately there are crystals that are neither perfect nor mosaic. In this case kinematic theory is applied and (strong) reflections, which have a reduced intensity, are corrected in a heuristic manner for “primary extinction”. Sometimes, even powders have to be corrected. Thus,
the following formulae are extreme cases. In practice, kinematic theory is applied except in the case of really perfect crystals. The secondary extinction can be reduced by quenching a crystal in liquid nitrogen.

The measured intensity $I(hkl)$ in the case of kinematic theory is given by Equation (66):

$$I(hkl) = K^2 \lambda^3 P_M|F|^2|H|^2$$

(66)

and $K$ is given by Equation (67):

$$K = \frac{e^2}{mc^2}$$

(67)

which involves the charge $e$ and mass $m$ of an electron and the velocity of light $c$.

In the case of dynamic theory, $I(hkl)$ is given by Equation (68):

$$I(hkl) = \frac{8}{3\pi}K^2\lambda^3 P_D|F||H|$$

(68)

Usually the proportionality factor, the product of $K$ and $\lambda$, is fitted as an independent parameter by the least-squares method. It is difficult to measure the intensity absolutely.

### 3.7 Diffuse Background

The diffuse background is produced by phonons and by defects in the crystal lattice. The intensity found in the background reduces the intensities of the Bragg reflections. The temperature factor assumes a statistically independent motion of the atoms owing to thermal motion. However, the phonons are waves traveling through the crystal with a broad spectrum of wavelengths that are multiples of the unit cell dimensions. They form superlattices in direct space that can be seen as a spectrum of very small peaks in reciprocal space. In other words, the reciprocal space is filled with intensity obtained by the diffraction of phonons. In general, only the phonons with low frequencies (i.e. the acoustic phonons) contribute to the diffuse background. Their intensity is concentrated around the Bragg reflections.

The defects of a crystal (e.g. stacking faults, interstitial atoms, etc.) also contribute to the diffuse background. In a crystal with defects, a mean unit cell is defined that is the average of the unit cells of the whole crystal. This is the periodic contribution to the electron density function of the whole crystal. The aperiodic contribution to the electron density is made by the defects.

By the mean unit cell, a mean structure factor $\langle F(hkl) \rangle$ is defined. The three-dimensional periodic mean unit cell gives a sharp Bragg reflection with an intensity $I_B(hkl)$ according to Equation (69):

$$I_B(hkl) \sim \langle F(hkl) \rangle^2|H|^2$$

(69)

where $|H|^2$ is the lattice function (Equation 65). The aperiodic contribution of the electron density creates a diffuse background $I_D(r^*)$ in the entire reciprocal space, according to Equation (70):

$$I_D(r^*) \sim \langle |F(r^*)|^2 \rangle - \langle F(r^*) \rangle^2$$

(70)

i.e. the intensity of the diffuse background is given by the fluctuation of the structure factor.

Gases, liquids, and amorphous materials give a diffuse and modulated diffraction pattern. Sharp reflections cannot be detected and a unit cell does not exist. The intensity is given by Equation (71):

$$I(\theta) = \sum_u \sum_v f_u f_v \frac{\sin k\Delta r_{uv}}{k\Delta r_{uv}}$$

(71)

where $v = (4\pi \sin \theta)/\lambda$, and $\Delta r_{uv} = |r_u - r_v|$ is the magnitude of the interatomic distance between atoms $u$ and $v$. Similarly to the Patterson function (Equation 45), a pair correlation function can be determined and in simple cases can be interpreted.\(^{35}\)

### 4 PRODUCTION OF X-RAYS AND THEIR CHARACTERISTICS

#### 4.1 The X-ray Tube

An X-ray tube is shown schematically in Figure 17. The X-rays are usually produced in an evacuated tube. The cathode is a tungsten filament, heated to emit
electrons. The cathode is at a negative potential in the range $-5$ to $-60 \text{kV}$. The anode is grounded at ground potential. Under this potential difference, the electrons are accelerated and hit the anode. Most of the energy heats the anode, which must be cooled by water. To increase the heat load on the anode without melting, the rotating anode was developed. The X-rays are produced in the anode (Figure 18). There are mainly two effects that produce X-rays in the anode with high intensity (Figure 19).

4.1.1 The Characteristic Radiation

The production of X-rays is the consequence of a collision between an accelerated electron and an electron bonded in the atom. The bonded electron is pushed out of the shell and expelled into the conduction band, leaving a hole in the shell. After this, the hole is refilled by an electron from an outer shell. The gain in potential energy is emitted as radiation. Because the electrons occupy precise potentials in the atom, a discrete spectrum is produced. In the case of X-rays, the hole must be produced in the innermost shell, the K-shell. The $\alpha$-radiation results from the transition of an electron from the next shell: the L-shell. The $\beta$-radiation results from the transition of an electron from the next highest shell: from the M-shell to the K-shell. The K$\alpha$ radiation is a doublet. The two lines indicate that the transition can be associated by a spin flip. The radiation is characteristic of the material of the anode.

4.1.2 Bremsstrahlung

Bremsstrahlung can be treated by classical electrodynamics. Each electric charge accelerated in a field emits radiation. The radiation is proportional to $\sin^2 \delta$, where $\delta$ is the angle between the velocity vector of the charge and the vector of acceleration, i.e. the radiation is maximal normal to the direction of the acceleration. The electrons entering the anode are accelerated and deflected by the electric field of the anode. This is a statistical process. When the electrons decelerate, they lose energy. The lost energy is emitted in the form of a continuous X-ray spectrum in all directions. The spectrum ends at low wavelengths when the total kinetic energy of an electron of the X-ray tube is converted into one phonon. The limiting wavelength $\lambda_1$ (in Å) is given by Equation (72):

$$\lambda_1 = \frac{12.398 \, U}{U}$$

where $U$ is the voltage of the X-ray tube (in kV). This relation is important if one wants to obtain a spectrum free of $\lambda/2$ or $\lambda/3$ of the characteristic radiation.

4.2 Synchrotron Radiation

A synchrotron is an accelerator for electrons. As a source for synchrotron radiation, storage rings are used, i.e. a ring in which electrons (or positrons) are kept moving. The energy of the electrons is in the range $1–5 \text{GeV}$, which is a factor of $10^6$ larger than in the X-ray tube. A bending magnet is needed to keep the beam of electrons on the path of the ring. Each magnet accelerates the beam radially, and thus the bremsstrahlung is created. However, owing to the high kinetic energy, relativistic electrodynamics must be applied. The characteristics of synchrotron radiation are very different from those of the bremsstrahlung of the X-ray tube.
5 DIFFRACTOMETERS AND CAMERAS

5.1 The Resolution Function

The fwhm of a reflection or a powder line is a function of the angle $\theta$ (Figure 20). It depends on the diffractometer, i.e., the geometry of the sample, the divergence of the primary beam, and the bandwidth $\Delta \lambda / \lambda$ of the X-rays. The function in Equation (73) was found experimentally\(^{36,37}\)

$$\text{fwhm} = U \tan^2 \theta + V \tan \theta + W$$  \hspace{1cm} (73)

where $U$, $V$, and $W$ are parameters that can be fitted by a least-squares procedure. The parameter $W$ is essentially defined by the cross-section of the incident beam or the diameter of the sample. The parameter $V$, which is a negative number, depends on the divergence of the primary beam together with the width of the mosaic spread of the sample, and $U$ depends mainly on the wavelength resolution $\Delta \lambda / \lambda$. The resolution function is valid for almost all diffractometers but the coefficients vary even from sample to sample.

5.2 Single-crystal Methods

In order to obtain the full information contained in an X-ray pattern, the intensities of all reflections $hkl$ have to be determined. This can be done only by the single-crystal methods. In a powder diffraction pattern or a rotation photograph, reflections usually superimpose. The photographic methods were developed to resolve superimposed reflections and facilitate the indexing of reflections. From the measurements, i.e. the size of the unit cell, the symmetry elements determining the Laue class, and the reflection conditions, the reciprocal lattice is obtained. In rare cases the space group can be determined uniquely by this information. The measurement is completed when each reflection is labeled by the indices $hkl$; its intensity profile is measured and integrated. If the symmetry is known, one may measure only the intensities in the asymmetric unit of reciprocal space and save the time of measurement of symmetrically equivalent reflections. However, the assumption of the symmetry may be biased or the sample may be twinned.

In the next section a short introduction is given to the different experimental methods by using the Ewald construction (section 3.3) and the reciprocal lattice. It should be noted that in the drawings the reciprocal lattice is exaggerated (large) in comparison with the dimensions of the screens, film cylinders, etc. found in the same figure. It is the angles that should be visualized, not the distances.

5.2.1 The Laue Method

The Laue method uses the continuous X-ray spectrum. The region of wavelengths $\lambda$ is limited at the short end of the spectrum by $\lambda_{\text{min}}$, which is governed by the high voltage applied to the X-ray tube (Equation 72). At the long end, the spectrum is limited by $\lambda_{\text{max}}$, owing to the absorption of the X-rays on the beam path by the window of the tube, by the air, or within the sample.

In Figure 21 the Ewald construction of the Laue method is shown schematically. The crystal and its reciprocal lattice are stationary. The direction of the incident beam $s_i$ within the reciprocal lattice is defined by the orientation of the crystal with respect to the incident beams. The end-points of the vectors $s_i$ are fixed at the origin of the reciprocal lattice, that is, at the lattice point of the reflection $h, k, l = 0, 0, 0$. The moduli of the vectors $s_i$ are $1/\lambda$. According to the range of wavelengths, $1/\lambda_{\text{min}}$ to $1/\lambda_{\text{max}}$, the vectors $s_i$ start on the line that is enclosed in Figure 21 by a rectangle. Each point on the line is the center of a sphere of reflection with radius $1/\lambda$. Thus, all lattice points between the spheres with radii $1/\lambda_{\text{min}}$ and $1/\lambda_{\text{max}}$ reflect simultaneously.

A special case is the reflections that originate from lattice points lying on a line passing through the origin. In Figure 21 two vectors, $s_{f1}$ and $s_{f2}$, are drawn that fulfill this condition. The two lattice points are situated in the region between the limiting spheres with the radii $1/\lambda_{\text{min}}$ and $1/\lambda_{\text{max}}$. The vectors $s_{f1}$ and $s_{f2}$ are parallel. The reflection angle $2\theta$ is equal in both cases. Thus, both lattice points reflect simultaneously in the same direction. The reflections, created by different wavelengths, superimpose on an X-ray film. By using an energy-dispersive detector the two reflections can be separated.

The Laue method is used to adjust crystals. The crystal, glued on a glass fiber, is fixed on a goniometer head that has two sliding carriages perpendicular to each other to center the crystal; the goniometer head also has two arcs perpendicular to each other, to turn the crystal into the

![Figure 20](Image) The shape of the resolution function (Equation 73).
one can observe the reflections of the Ka filter. When filtered radiation is recorded by a film, By using a monochromator (i.e. reflection by a net on top of the streaks of the continuous spectrum. It is often sufficient to remove the Kb radiation by reducing the high tension of the X-ray tube (Equation 72) or by using a double-crystal monochromator.

5.2.2.1 The Four-circle Diffractometer

The four-circle diffractometer is the most important instrument to use for measuring the intensities from single crystals. One circle is used to position the detector at the Bragg angle 2θhkl; usually this circle is horizontal. Three additional circles are needed to turn a reciprocal lattice point into the diffraction plane, the plane of the 2θ-circle, and to sweep the lattice point through the reflection circle. There are two types of instruments on the market:

1. The four circles of the Eulerian cradle are 2θ, ω, χ, and ϕ. The cradle is shown in Figure 22(a). The 2θ-axis, supporting the detector, coincides with the incident beam. From Laue photographs, taken from the symmetry directions of the crystal, the Laue class can be determined. The adjusted crystal can be used in further investigations.

Laue diagrams usually are not used to determine the intensities of reflections. In the spectrum of an X-ray tube, the intensities vary too much with the wavelength. This is different in the case of synchrotron radiation, where the intensity is almost constant over a large range of wavelengths. By using two-dimensional position-sensitive detectors, the intensities of many reflections are determined simultaneously. The Laue method is of great advantage in protein crystallography, where the samples of biological material have only a short lifetime. The intensities of many reflections can be measured simultaneously in a short time and only a few reflections superimpose.

5.2.2 Monochromatic Methods

The indexing of the reciprocal lattice is simplified if one uses monochromatic radiation. Using an X-ray tube, it is often sufficient to remove the Ka radiation by a filter. When filtered radiation is recorded by a film, one can observe the reflections of the Kb radiation on top of the streaks of the continuous spectrum. By using a monochromator (i.e. reflection by a net plane of a single crystal), monochromatic radiation is obtained. This radiation can be spoiled by higher harmonics of the wavelength (i.e. λ/2 and λ/3), which give additional reflections on a film. This radiation can be removed by reducing the high tension of the X-ray tube (Equation 72) or by using a double-crystal monochromator.

![Ewald construction of a Laue diagram](image)

**Figure 21** The Ewald construction of a Laue diagram. The range of wavelength is limited by two spheres of reflection with radii 1/λ_{min} and 1/λ_{max}. All lattice points between the two spheres fulfill the reflection condition. The vectors s_1 and s_2 indicate the momenta of two reflected waves represented by two lattice points lying on a line passing through the origin of reciprocal space. The vectors s_4 and s_2 are parallel and reflect under the same diffraction angle 2θ. Thus, the reflections superimpose.

Intensities are measured in two ways. In the first method, the 2θ-circle and the ω-circle scan simultaneously, the latter with half-speed (θ, 2θ scan). In reciprocal space, this corresponds to a motion along a line passing through the origin. The scan follows the trace of the reflections produced by the white radiation of the X-ray tube. The contribution of the white radiation is subtracted as background from the intensity of the Ka reflection. In the second method, the detector (with a sufficiently opened entrance slit) is kept stationary and the crystal is turned by the ω-circle. In reciprocal space, this corresponds to a motion of the reciprocal lattice point on a circle with radius r = 1/d_{hkl}. This method is applied in the case of the background radiation produced by the material around the sample, e.g. a capillary. In this case the intensity of the material is subtracted as background from the measured intensity.
The four-circle diffractometer is a universal instrument. With an x,y sliding carriage on the ϕ-circle, the texture on the surface of large platelet samples is also investigated.

The adjustment of a crystal on the diffractometer has been described for an instrument with a Eulerian cradle. In the case of a kappa diffractometer the procedure is similar. It is advantageous to know the lattice constants, the indices of strong reflections, and the approximate orientation of the sample at the start of the adjustment. The procedure is easy in the case of a sample with an orthogonal unit cell. The angle χ is set to 90°. Let the c-axis of the crystal be approximately parallel to the ϕ-axis of the diffractometer. A reflection 001 of a lattice plane at known 2θ, which is expected to be normal to the ϕ-axis, can be found by scanning the w-circle. The offset of the crystal from the w-axis is stored as an offset of the χ-circle in the computer. In a second step, the ϕ-circle is turned by 90° and the procedure is repeated. The offset is stored as an offset of the w-axis. Now the orientation of the c-axis with respect to the ϕ-circle is known. The χ-axis is turned by 90° and reflections are searched in the plane perpendicular to the ϕ-axis. This defines the zero point of the ϕ-circle. The adjustment is correct when addition reflections are found. In a special procedure, the positions of a set of reflections are measured automatically to refine the orientation matrix by least squares, i.e. the orientation and the measured lattice constants. The adjustment of a crystal with an anorthic unit cell is more difficult.

There are computer programs for the automatic search of reflections. However, reflections with low intensity are easily overlooked. This may result in too large a unit cell in reciprocal space, i.e. too small a unit cell in direct space. Also, twinning is difficult to detect by the use of a four-circle instrument, therefore each sample should be investigated in advance by photographic methods to determine the lattice constants and, as far as possible, the space group. The crystal, already oriented on a goniometer head, can be transferred easily from the photographic camera to the diffractometer and it is easy to adjust the small deviations that may have occurred during the transfer.

5.2.2.2 Photographic Methods

Photographic methods permit the planes of reciprocal space to be investigated and indexed. For the rotation or Weissenberg method, a lattice plane is adjusted normal to the rotation axis, i.e. the axis of the goniometer head. Planes normal to the rotation axis are investigated. However, the precession method investigates planes parallel to the rotation axis. Usually the Weissenberg photograph is made with Cu Kα radiation. The precession pattern is obtained by Mo Kα radiation so that the radii of reciprocal space, explored by the two methods, are approximately equal and the two methods are complementary. A crystal with an orthogonal unit cell, adjusted in a Weissenberg camera, can be transferred immediately to a precession camera, and vice versa. It is easier to adjust a crystal in a Weissenberg camera than in a precession camera. The great advantage of the precession camera is to give an undistorted picture of reciprocal lattice planes.

5.2.2.3 The Rotation Method

The cross-section of a rotation camera is given in Figure 23. Usually, the radius of the cylindrical film is \( r_F = 90°/\pi = 28.649 \) mm. One millimeter on the circumference of the film corresponds to an angle of 2°. A single crystal mounted on a thin glass rod on the goniometer head is placed at the middle of the film cylinder. The crystal is rotated and the rotation axis is perpendicular to the incident beam. A rotation photograph is shown schematically in Figure 24.
STRUCTURE DETERMINATION, X-RAY DIFFRACTION FOR

Figure 23 Cross-section of a rotation camera: C, collimator; S, sample; B, beam stop; F, cylindrical film or position-sensitive detector or circle on which the entrance slit of a detector scans.

Figure 24 Schematic drawing of a rotation photograph of a hexagonal crystal: c-axis vertical.

The crystal is adjusted if the normal of a plane of lattice points is parallel to the rotation axis, i.e. the incident beam passes this plane of lattice points independently of the rotation angle \( \omega \). For example, if the c-axis of the crystal is adjusted so that it coincides with the rotation axis, the plane \( hkl0 \) is normal to the cylinder axis of the camera and coincides with the incident beam. On a photograph with a well-adjusted crystal, the reflections appear on layers ordered according to the aligned axis. In the example with the c-axis parallel to the rotation axis, the layers are \( hkl0, hk1, hk2, \) etc.

The reflection geometry can be seen in Figure 25. On the X-ray film, the distance of the \( n \)th layer line from the zero layer is \( y_n \). The angle \( \nu_n \) is obtained by Equation (74):

\[
\tan \nu_n = \frac{y_n}{r_F} \tag{74}
\]

where \( r_F \) is the radius of the film cylinder. The distance \( d_n^* \) of the \( n \)th net plane to the zero plane in reciprocal space normal to the rotation axis is given by Equation (75):

\[
d_n^* = \frac{1}{\lambda t} \tag{75}
\]

where \( t \) is the translation of the crystal in the direction of the adjusted axis. From Figure 25 Equations (76) and (77) can be derived:

\[
d_n^* = \frac{1}{\lambda} \sin \nu_n \tag{76}
\]

\[
d_n^* = \frac{1}{\lambda} \sqrt{r_F^2 + y_n^2} \tag{77}
\]

Thus, the lattice constant of the adjusted axis can be determined from the rotation photograph directly by Equation (78):

\[
t = \frac{\lambda}{\mu y_n} \sqrt{r_F^2 + y_n^2} \tag{78}
\]

As in a powder diffraction pattern, reflections superimpose within the layer lines. Owing to the rotation, there are two mirror planes in the photograph; the vertical plane is produced by the rotation, and the horizontal plane relates reflections \( hkl \) with reflections \( hkl \). Owing to this effect, the symmetry information is obscured.

It is difficult to index a set of reflections if the crystal is not properly adjusted. The procedure for aligning a crystal is described in the legend of Figure 26.

5.2.2.4 The Weissenberg Method

The Weissenberg method was developed to separate the superimposed
Figure 26 A zero layer line misoriented by the angles $\alpha$ and $\beta$. One arc of the goniometer head is placed parallel and the other arc is placed perpendicular to the incident beam. From the trace of lattice plane obtained by a Laue photograph in combination with a small oscillation $\Delta \omega$ of the crystal, the two correction angles $\alpha$ and $\beta$ can be determined. The angle $\alpha$ is read out from the photograph directly. The angle $\beta$ is obtained by the deviation $d$ of the lattice plane at $2\theta = 180^\circ$, i.e. $\tan \beta = d/2r_L$, where $r_L$ is the radius of the film cylinder; usually $\tan \beta = d/57.296$.

reflections within the layers of a rotation photograph. For each layer a Weissenberg picture has to be taken. The Weissenberg camera is a rotation camera (as shown in Figure 23) in which a cylindrical layer-line screen is inserted between the crystal and the film, which is shifted while the crystal is rotated. For nonzero layer photographs, the camera is inclined with respect to the incident beam by the angle $\mu_e$.

5.2.2.5 The Zero Layer At first the technique is explained for the zero layer, which is seen on the equator of a rotation photograph. The incident beam is normal to the rotation axis. A cylindrical screen permits only the rays of the zero layer line to pass to the cylindrical film (Figure 27). Simultaneously with the rotation of the crystal, the film is shifted parallel to the rotation axis. After a rotation of more than $180^\circ$, the rotation of the crystal and the motion of the film are reversed. On the film, the position of a reflection is recorded as a function of $w$ and $2\theta$ (Figure 28). The example shown in Figure 28 is the picture of a hexagonal $hk0$ plane, which is shown in Figure 11.

The shift of the film is coupled with the rotation angle by $2^\circ \text{mm}^{-1}$. A straight line passing through the origin of reciprocal space is recorded on the film also as a straight line. In a typical camera with the film radius $r_L = 28.649 \text{ mm}$, $\theta = 2^\circ \text{ mm}^{-1}$ and the straight line on the film is inclined by $63.43^\circ$. A line passing through the origin at a distance $d^*$ gives a line on the film defined by Equation (79):

$$\theta = w_0 \pm \arccos \left( \cos w + \frac{d^*}{\lambda} \right)$$  \hspace{1cm} (79)

A chart is drawn with parallel lattice lines appearing on a Weissenberg photograph. The use of the chart is shown in Figure 28. Each reflection lies at the intersection of two lines relating two indices, say the indices $h$ and $k$ in an $hk0$ reciprocal lattice plane.

5.2.2.6 The Equi-inclination Method With the Weissenberg camera, the nonzero-layer lines are also investigated. The most comfortable way is the equi-inclination method. From the rotation photograph the angle $\nu_n$ is obtained, the angle between the zero layer line on the film and the $n$th layer line. For the equi-inclination method, the Weissenberg camera is inclined by $\mu_e$, given by Equation (80):

$$\mu_e = \arcsin \left( \frac{1}{2} \sin \nu_n \right)$$  \hspace{1cm} (80)

and the layer-line screen is shifted according to Equations (81) and (82):

$$s_L = r_L \tan \mu_e$$  \hspace{1cm} (81)

$$s_L = \frac{r_L \sin \nu_n}{\sqrt{4 - \sin^2 \nu_n}}$$  \hspace{1cm} (82)

where $r_L$ is the radius of the screen. Thus, the angle between the incident beam $s_i$ and the zero layer is $\mu_e$, i.e. the same as the angles between the reflected beams and the zero layer $\nu_e$ (equi-inclination; Figure 29).
The advantage of this method is that the $n$th layer line is recorded on the film in almost the same way as the zero layer line. The same chart can be used to index the reflections. However, the scale is changed. In the zero layer line the angle $2\theta$ was recorded as a function of the rotation angle $w$ of the crystal; in the $n$th layer line the angle $2\sigma$ is recorded as a function of $w$. The relation between these angles is given by Equation (83): \[
\cos 2\theta_{hk0} = \cos 2\sigma \cos \mu_c \quad (83)
\]
The relation is easily derived by spherical trigonometry. The equation of a line at a distance $d^*$ from the intersection of the rotation axis with the $n$th layer in reciprocal space must be modified. These
Figure 29 Schematic drawing of an equi-inclination Weissenberg photograph. The angle of the incident beam with the equatorial plane $\mu$ and the angle of the reflected beam with the equatorial plane $\nu_r$ are equal, where $\mu = \nu_r$. The sine of the angle $\nu_r$ is half of the sine of the angle $\nu_0$, which was obtained from the rotation photograph. Thus only the reflections $s_f$ of the upper lattice plane can pass the slit of the layer line screen ($L$), the gap between two cylinders. With the rotation of the crystal by the angle $w$, the cylindrical film $F$ is shifted parallel to the rotation axis ($A$).

Figure 30 Schematic drawing for the reflection conditions of a zero layer line of a precession photograph. $L$ is the layer-line screen; $F$ is the film; $O^*$ is the origin of reciprocal space, which is projected onto the film at $O$; $\mu$ is the angle of inclination of the camera; and $r_c$ is the radius of the circle by which the reflecting net plane (dotted line) intersects the sphere of reflection.

In order to obtain a total map of the $0kl$ plane, all possible circles that can be obtained by an inclination $\mu$ have to be scanned through the sphere of reflection. This is obtained by a motion by which the normal of the lattice plane $0kl$, fixed at the origin $O^*$, moves on a cone with an opening angle of $2\mu$.

The cone of reflected beams emanates at the center of the sphere of reflection. From this point a circle of the reciprocal lattice plane is projected onto the film. In order to obtain an unperturbed map, the film must be kept parallel to the reflecting net plane $0kl$, i.e. the film has to perform the same motion with $O$ as a fixed point as the lattice plane does with its origin $O^*$ as a fixed point. In Figure 31 are shown projections of cones obtained by the intersection of the net plane with the sphere of reflection. The radii $r_c$ of the circles on the film are as shown in Equation (86):

$$r_c = M \sin \mu \quad (86)$$

where $M$ is the magnification factor, i.e. the distance from the center $O$ of the film to the center of the sphere of reflection, which is usually 60 mm. A reciprocal lattice point on the net plane at a distance $r_{hk\ell}$ from the origin $O^*$ is projected onto the film at a point that is at the distance $s_{hk\ell}$ from $O$, the center of the film (Figure 31). The relation between $r_{hk\ell}$ and $s_{hk\ell}$ is given by Equation (87):

$$2M \sin \theta_{hk\ell} = \lambda Mr_{hk\ell} = s_{hk\ell} \quad (87)$$
Figure 31  The picture of the layer-line screen at four moments of the motion, permitting a cone of reflected intensity to pass to the film. The incident beam could pass the screen as reflection $hkl = 0, 0, 0$ at $O$, which is prevented by the beam stop. By the motion of the camera the cone of reflected intensity moves and covers the film. The envelope of all reflected cones has the radius $r_B$; $s_{adj}$ is the distance of a reflection $hkl$ from the origin $O = 0, 0, 0$.

In order to protect the film from reflections of other layers, a screen is inserted. The screen has a transparent circle with a given radius $r_s$, usually 15, 20, 25, or 30 mm. The screen is attached to the axis of the crystal at a distance $S_L$. When the inclination $\mu$ and the radius $r_L$ are chosen, the screen has to be set at a distance given by Equation (88):

$$S_L = \frac{r_L}{\tan \mu} \quad (88)$$

The lattice plane is mapped onto the film within the radius given by Equation (89):

$$r_B = 2M \sin \mu \quad (89)$$

Outside $r_B$ is a blind region where no reflections are found.

Before a precession photograph can be taken, the angle $\mu$ of the instrument must be set to zero and the normal of the lattice plane to be observed must be oriented parallel to the direction of the incident beam. There are three angles to adjust for the crystal: the two arcs of the goniometer head and the angle $\phi$ of the axis on which the goniometer head is mounted (Figure 32). A first overview can be obtained by a Laue picture without a screen. The parameters of the correction of small deviations are found in precession photographs with a small precession angle, specifically $\mu = 10^\circ$, and a layer-line screen with a circular hole of 10 mm. The effect is shown in Figure 33. In this picture the crystal has to be adjusted by a turn around the horizontal axis by the
5.2.3.2 The Upper-level Layer

The distance of the nth layer from the origin is \( d_n = 1/nt \), where \( t \) is the translation of the crystal. The distance of the zero layer from the center of the sphere is \((\cos \mu)/\lambda\) (Figure 34).

A horizontal deviation is corrected correspondingly.

\[
\Delta \varphi = \frac{d_1 - d_n}{M} \quad (90)
\]

The distance of the nth layer is thus \((\cos \mu)/\lambda - d_n\), as in Equations (91) and (92):

\[
\frac{\cos \nu}{\lambda} = \frac{\cos \mu}{\lambda} - d_n' \quad (91)
\]

\[
\sin \nu = \sqrt{1 - \left(\frac{\cos \mu - \lambda d_n'}{\lambda}\right)^2} \quad (92)
\]

The radius \( r_{en}' \) of the circle obtained by the intersection of the nth layer with the sphere of reflection is given by Equation (93):

\[
r_{en}' = \frac{\sin \nu}{\lambda} \quad (93)
\]

Thus, the screen with radius \( r \) has to be placed at a distance \( s_s \) from the crystal, as shown by Equations (94) and (95):

\[
s_s = \frac{r_s}{\tan \nu} \quad (94)
\]

\[
= r_s \frac{\cos \mu - \lambda d_n'}{\sqrt{1 - \left(\frac{\cos \mu - \lambda d_n'}{\lambda}\right)^2}} \quad (95)
\]

The nth lattice plane is at the distance \( d_n' \) from \( O' \). In order to obtain an unperturbed projection of the lattice plane, the film must also be shifted from \( O \) toward the crystal as given by Equation (96):

\[
s_F = d_n'M\lambda \quad (96)
\]

The motion of the film relative to the origin \( O \) must be similar, in the mathematical sense, to the motion of the nth lattice plane relative to the center of reciprocal space \( O' \). The distance \( s_{hkl} \) of a reflection \( hkl \) from the origin of the film is related to \( r_{hkl}' = 2(\sin \theta_{hkl})/\lambda \) as shown by Equations (97) and (98):

\[
r_{hkl}' = \sqrt{(d_n')^2 + \frac{s_{hkl}^2}{\lambda M}} \quad (97)
\]

\[
= \frac{1}{\lambda M} \sqrt{s_F^2 + s_{hkl}^2} \quad (98)
\]

The lattice plane is mapped on the film within the radius as shown by Equation (99):

\[
r_B = M(\sin \nu + \sin \mu) \quad (99)
\]

which is the radius of the blind region (Figure 35). However, there is another blind region in the center of the precession photograph with the radius as shown by Equation (100):

\[
r_B = M(\sin \nu - \sin \mu) \quad (100)
\]

The mechanics of a precession camera are shown in Figures 32 and 36. The crystal (C) is positioned in the center of two perpendicular rotation axes to enable a
precession motion. Two other rotation axes intersect in the zero point of the film ($F'$). By using a rod, the motion of the crystal is coupled to the motion of the film. With $\mu = 0$, the reciprocal lattice of the crystal and the plane of the film are normal to the incident X-ray beam, the direction of which coincides with the motor axis. With $\mu = 0$, the crystal and film do not move when the motor rotates. With $\mu \neq 0$, the crystal and film perform a precession motion, i.e. the normals of the crystal in $O$ and the film in $O'$ yield a cone with an opening angle $2\mu$. On varying $\varphi$, the holder for the layer screen ($L$) is fixed. Its distance from the crystal can be set by using the scale $s_L$. For photographs of higher levels, the film must be shifted from the zero point ($O$) toward the crystal. The distance can be read out on the scale $s_F$. (The precession camera was invented and described by Buerger.\textsuperscript{38})

5.3 Powder Diffraction

The diffraction of a single crystal was described by the reciprocal lattice, which consists of mathematical points. However, all reflections have a profile, even those of a perfect crystal. In a mosaic crystal the domains are slightly misoriented, which can be measured by the broadening of the reflections: the mosaic spread. There are various possible transitions between a perfect crystal and a randomly oriented sample such as a powder. A statistically preferred orientation is called a texture, which can be measured by using a four-circle diffractometer. The detector is set at a value of $2\theta$ for a Bragg reflection and the distribution of the reflected intensity in reciprocal space is measured. There are textures of rotational symmetry in fibers or wires, and textures on the surface of rolled material. Even powders may have a texture. For example, clay minerals prepared on a flat surface lie parallel. This is used to identify the different modifications according to their $c$ lattice constant normal to the plane of preparation. It is sometimes very difficult to measure the correct intensities of a powder pattern owing to texture. Texture is immediately observed in a Debye–Scherrer photograph (Figure 37). With a powder diffractometer one is often not aware of the effect. The effect of texture can be reduced by spinning the sample.

Figure 35 The picture of the layer-line screen at four moments of the motion of an upper-level photograph. The four circles are produced by the cones of reflected intensity that can pass to the film. In the center of the picture a blind region occurs; the inner envelope of the motion of the circles.

Figure 36 Schematic drawing of the top view of a precession camera. The motor ($M$) drives the precession motion, i.e. a cone with the opening angle $\mu$ (in the drawing 20°). The film ($F$), the layer-line screen ($L$), and the lattice plane of the crystal ($C$) are always parallel, $s_L$ is the scale for the distance of the screen from the crystal; $s_F$ is the scale for the shift of the film from the zero point, and the path of the incident beam is indicated by a dotted line.

Figure 37 Powder diffraction pattern of a copper wire showing texture.
Powder diffraction is mainly used to identify crystalline phases. Structure determination by X-ray powder diffraction has become an important field. There is usually enough material for a powder sample and a powder diagram is easily obtained experimentally.

In Figure 38 the Ewald construction for powder diffraction is shown. The isotropic distribution of the crystals in the sample produces spheres of reflecting net planes with the radius \( r = 1/|d_{hkl}| \) in reciprocal space, i.e. the lattice points \( hkl \) are smeared out to spheres. The sphere of one powder line \( hkl \) with the Bragg angle \( 2\theta_{hkl} \) intersects the sphere of reflection in a circle. From the center of the sphere of reflection opens a cone of diffraction with an opening angle of \( 4\theta_{hkl} \). This angle is observed in a Debye–Scherrer camera.

Figure 38 Reciprocal space of a powder with an fcc structure. The reciprocal lattice points of the powder are randomly oriented on spheres as indicated by dotted lines. The intersection of the sphere \( hkl = 111 \) with the sphere of reflection results in a cone, emanating from the center of the circle of reflection, with an opening angle of \( 4\theta_{111} \). This angle is observed in a Debye–Scherrer camera.

5.3.1 The Debye–Scherrer Method

A schematic drawing of the Debye–Scherrer geometry is given in Figure 39. The advantage of the method is that all powder lines can be recorded simultaneously. The resolution \( \Delta \theta/\theta \) is determined by the divergence of the primary beam and the radius \( r \) between the sample and the detector. However, if one improves the resolution by enlarging this radius \( r \), the observed intensity is reduced, being proportional to \( r^{-2} \). Well-ground powder is filled into a capillary, which is centered in the middle of the device. In order to improve the statistics (i.e. the homogeneity of the diffraction pattern), the sample is spun. In the case of a photographic camera, a cylinder containing the film is placed around the sample. The radius \( r \) of the camera is chosen to be \( n \times r = 28,648 \) mm, so that 1 mm on the film is equal to \( 2\theta/n \). Today the film is replaced by a position-sensitive detector. In the case of a Debye–Scherrer diffractometer, a counter or a counter bank sweeps at a constant distance around the sample.

5.3.2 The Bragg–Brentano Diffractometer

The resolution of the Debye–Scherrer method was improved by the invention of the Bragg–Brentano diffractometer. This is a parafocusing method. The resolution is improved in the region of the focus, but elsewhere the resolution is reduced. Thus, only one powder line and its environment can be detected simultaneously. The diffractometer is shown schematically in Figure 40. The flat sample is rotated by an angle \( \theta \) while the detector is rotated by an angle \( 2\theta \) around the axis common to both circles. The distance from the X-ray source to the sample is equal to the distance from the sample to the entrance slit of the detector. The focusing circle is defined by the following three points: the source, the center of the sample, and the entrance slit of the detector. The flat sample is positioned tangential to the focusing circle. The focusing condition is fulfilled only for the points on the focusing circle. Thus, the sample obeys only a parafocusing condition. The resolution is mainly given by the divergence of the X-ray beam and the source–sample distance or the source–detector distance. The divergence normal to the diffraction plane is improved by Soller slits: a set of parallel foils of strongly absorbing material at an equal distance from one another. Owing to the lines of the Ka spectrum, the reflections are broadened in the range of small \( 2\theta \) and split at high \( 2\theta \). One can suppress the Ka radiation by placing a
monochromator after the source. The fluorescent radiation produced in the sample by the primary beam can be removed by inserting a monochromator in front of the detector.

14 Conclusions and Outlook

Total reflection X-ray fluorescence (TXRF) analysis is an energy-dispersive (ED) X-ray fluorescence (XRF) technique using a special excitation geometry. The narrow collimated beam impinges at grazing incidence on a special sample carrier. This is a flat polished quartz plate on which the sample is deposited. The most significant advantages of TXRF over conventional XRF analysis are the improved detection limits achieved by inherent signal increase and reduced background. Detection limits are in the picogram range for X-ray tube excitation and even down to femtograms for excitation using synchrotron radiation (SR). The main application is the analysis of some microliters of a liquid sample deposited and dried on the quartz reflector or of some microliters of slurry or microgram grains of solid samples. The most widely used application is the quality control of contaminations on Si wafer surfaces. The detection limits demanded by the semiconductor industry can be reached today using X-ray tube excitation, but metrology shows that in the future SR is required or special preconcentration techniques. Straight TXRF is the only analytical technique offering nondestructive and spatial resolved analysis. A special ED detector with an ultrathin window is suitable for the detection of low atomic number, Z elements (C upwards) using TXRF. Another promising application is the characterization of thin layers on a reflecting surface or implanted atoms in Si by variation of the incidence angle and measurement of the fluorescence signal. It is possible to determine the elements forming the layer, the layer thickness and its density. For thin layered samples as well as implantations, thickness, depth and depth profile for implanted atoms can be evaluated by comparing experimental results with theoretical models.

1 INTRODUCTION

1.1 Physical Principles

XRF analysis is a powerful analytical tool for the spectrochemical determination of almost all the elements...
present in a sample. XRF radiation is induced if photons with sufficiently high energies emitted from an X-ray source impinge on the sample. These primary X-rays undergo interaction processes with the atoms of the analyte. Taking Bohr’s model of the atom as a basis to explain the mechanism of the excitation and creation of fluorescence radiation, this process can be described as follows. High-energy photons induce ionization of inner shell electrons by the photoelectric effect and thus electron holes in the innermost K shell or the L or M shells are created. After the interaction the photoelectron leaves the atom carrying the difference energy of incident photon energy minus the binding energy of the specific shell electron which was expelled. The prompt transition of outer shell electrons into the vacancies within some 100 fs causes emission of characteristic fluorescence radiation to take place. Not all transitions from outer shells or subshells are allowed, only those obeying the selection rules for electric dipole radiation. All the excited atoms of each element in the sample emit their characteristic X-rays. An electron transition following the electric dipole selection rules, from e.g. L_{III} to K, fills up the K shell but leaves the L shell with an electron hole. This L shell vacancy is again filled by another transition (e.g. M_{V} – L_{III}) and so on until the last outer shell vacancy is filled from the pool of free electrons always present. The result is a cascade of electron transitions all correlated with the emission of photons with a well-defined energy corresponding to the difference in energy between the atomic shells involved. The X-ray family of characteristic X-rays from each element including all transitions allows the identification of the element. In fact XRF is not the only possible process following the electron transitions from higher energy levels to the lower energy states. There is a competing process associated, the emission of Auger electrons. Both processes have certain Z-dependent probabilities which are complementary: Auger yield is high for light elements and fluorescence yield is high for heavy elements. The determination of Auger electron energy and intensity also allows spectroscopy to identify the elements but is not considered here.

1.2 X-ray Fluorescence Analysis

The working principle of XRF analysis is the measurement of wavelength or energy and intensity of the characteristic photons emitted from the sample. This allows the determination of the elements present in the analyte and their mass or concentration. All the information for the analysis is stored in the measured spectrum, which is a line spectrum with all the characteristic lines superimposed above a certain fluctuating background. The background is induced by other interaction processes, mainly the elastic and inelastic scattering of the primary radiation on sample and substrate. Detailed information about XRF analysis is given in the literature.\(^{(1–3)}\)

Measurement of the spectrum of the emitted characteristic fluorescence radiation is performed using wavelength-dispersive (WD) and ED spectrometers. In wavelength-dispersive X-ray fluorescence (WDXRF) analysis the result is a spectrum intensity of the characteristic lines versus wavelength measured with a Bragg single crystal as dispersion medium and counting the photons with a Geiger-Müller, proportional or scintillation counter. In energy-dispersive X-ray fluorescence (EDXRF) analysis the photon energy is directly measured by a suitable detector which selects the photons due to energy and counts them directly and stores the result in a multichannel memory. The result is a spectrum with intensity on the y-axis and energy on the x-axis. The range of detectable elements is limited. It ranges from Be (Z = 4) for the light elements and goes up to U (Z = 92) on the high atomic number Z side. The concentrations that can be determined with standard spectrometers of both types WD or ED lie between micrograms per gram and weight percent, thus having a wide dynamic range. In terms of mass the nanogram range is reached with spectrometers that have excitation geometry typical of incident primary radiation (45° to the flat sample surface).

In the course of the developments and improvements which are discussed in this chapter, by introducing special excitation geometry, optimized sources and detectors, picogram and even femtogram ranges for the detection limits were reached and in terms of concentration the same improvement factor was attained from microgram per gram to picogram per gram under the best conditions. In principle, XRF analysis is a multielement analytical technique and in particular, the simultaneous determination of all the detectable elements present in the sample is inherently possible with EDXRF. In WDXRF both the sequential and the simultaneous detection modes are possible.

1.3 Features of X-ray Fluorescence Analysis

What are the defining features of XRF analysis? It can be said that this analytical technique allows the qualitative and quantitative analysis of almost all the elements (Be – U) in an unknown sample. The analysis is in principle nondestructive, has high precision and accuracy, has simultaneous multielement capacity, requires only a short time, a high sample throughput is possible, on-line analysis is possible, running costs are low, is extremely versatile for applications in many fields of science, research and quality control, has low detection limits, and a large dynamic range of concentrations covering up to 10^9 orders of magnitude. The physical size of an XRF spectrometer ranges from handheld, battery-operated field units to...
high-power laboratory units with compact table top units and larger ones requiring several cubic meters of space including a 10–20 kW electrical power supply and efficient cooling units with high pressure water and a heat sink. In contrast to all these attractive properties there are some disadvantages. The absorption effects of primary radiation and the fluorescence radiation created in the analyte result in a narrow layer a few tenths of a millimeter wide which provides information from the source of the signal. This requires a perfectly homogeneous sample which often occurs naturally but must sometimes be produced by dissolution into liquids or by grinding and pressing pellets. In both examples the feature of nondestructiveness is lost. Most ideally thin films or small amounts of microcrystalline structure on any substrate are the ideal analyte where even the quantification process is simple because there is linearity between fluorescence intensity and concentration. In thick samples there is only a proportionality between intensity and concentration or mass of the element which requires calculations to correct for absorption and enhancement effects.

The interactions of primary X-rays create the fluorescence signal from the analyte. Considering the interactions only, the photoelectric effect is responsible for the creation of characteristic lines. However, this is not the only effect observed in this energy range of X-rays mainly used for XRF, namely to 60 keV or 100 keV. Elastic and inelastic scattering of the primary radiation are observed simultaneously on the sample itself and on the substrate. This results in a background in the measured spectrum upon which the characteristic lines are superimposed. The primary radiation displays a spectral distribution according to the way it was produced. An X-ray tube is most often in use where the direct beam shows a continuum (bremsstrahlung) and characteristic lines of the anode material. Figure 1 shows a spectrum emitted from an X-ray tube with a Mo anode and operated 45 kV and 3 mA. Owing to the scattering processes those photons scattered towards the detector will be registered in the same way as the fluorescence radiation and appear in the measured spectrum as background. This background is the limiting factor as the signal from lower and lower concentrations or masses will decrease proportionally, whereas the scatter background from the sample matrix or the substrate will remain the same. When a particular lowest mass or concentration value is reached the signal cannot be distinguished from the statistical fluctuations of the background, in other words the detection limits are reached. Ways of improving the detection limits are discussed in section 3.1.

A renaissance in XRF took place as the importance of trace element analysis in samples from environment, medicine and technology was clearly shown and because XRF was such a perfect candidate for a spectrochemical analytical technique.

The burden on the environment from natural or artificial sources requires the use of analytical techniques so that careful control of the emitters and what part is absorbed or accumulated in all forms of life can be maintained. Knowledge about the importance of trace amounts in the uptake from food, air, and water by humans requires reliable critical measurements at extremely low levels of concentration. Changes in the production and preparation of food has changed the uptake of essential trace elements by human beings, thus changing the levels of both biopositive and negative trace elements in body fluids, tissues, bones and organs. Medical diagnosis is supported by knowledge of the expected average levels of trace elements in the body and changes in the low microgram per gram levels can point to serious diseases. Medical treatment like chemotherapy can lead to overexposure of carrier elements in some organs which should be avoided to keep them working properly. The wide field of nanotechnology and microelectronics requires new levels of detectability in ultratrace amounts where femtogram levels must be considered because of the relevant damage they cause in the final device in reducing the production yield. The capability of detecting lower and lower masses or concentrations by the introduction of improved analytical techniques and methods opens up new applications and can have a new impact on science and technology.

2 HISTORY

On November 8th, 1895 Conrad Wilhelm Roentgen, at age 50, discovered X-rays. Within a few weeks he had performed in his laboratory at the University of Würzburg, Germany, a great number of experiments
with this “new kind of radiation”, which is the literal translation of his first publication in December 1895, Über eine neue Art von Strahlung. He found that X-rays had many properties, like ionization, transmission and absorption, blackening of photographic plates, as well as inducing fluorescence in the visible range of certain materials. Some other properties of the new kind of radiation like polarizability, refraction and reflection were tested by W.C. Roentgen in experiments but were not observed and thus declared to be nonexistent. Later C.G. Barkla in a series of experiments which he performed in 1906–1907, found that he could polarize X-rays by scattering on a piece of carbon through an angle of 90°. This constituted an important step on the way to explaining the true nature of X-rays by showing evidence that this property which is well known for visible light and electromagnetic transversal waves could be applied to X-rays. The true nature of X-rays as electromagnetic waves was certified 17 years after their discovery by the Munich research group of M. Laue, W. Friedrich and P. Knipping and later by the University of Cambridge scientist W.L. Bragg.

In all the early publications no experimental observation of refraction or reflection of X-rays was made, meaning that an important property which was expected to exist, as it did for visible light, was missing. In 1919 W. Stenström described in his thesis the observation of slight deviations from the calculated Bragg angles, in particular at diffracted peaks of higher orders, which he interpreted correctly as refraction phenomenon. Finally he concluded theoretically from this fact, that if reflection occurs then refraction must also be occurring and must be observable. The first experimental evidence of the effect of the “total reflection of X-rays” was confirmed and published by A.H. Compton in 1922.

The reason for the relatively late experimental verification is because the critical angles for the total reflection of X-rays are small, in the range of milliradians or tenths of a degree, and in contrast to light optical experiments the effect is observed for X-rays while they are passing from air or vacuum to matter, that is to say in the light optical sense into denser material. Experimentally the set-up was such that a narrow collimated X-ray beam was directed towards the top edge of a glass prism, thus giving a minimum of absorption, and the refraction–reflection phenomenon was observed at the tip, resulting in three split X-ray beams, one primary beam which passes on in the same direction and one passing above (the refracted beam) and one passing in between (the reflected beam), all registered on a photographic plate. Figure 2 shows a sketch of the experimental set-up.

On the photographic plate the three split beams were observed well. This experiment was performed by A. Larsson, M. Siegbahn and J. Waller in 1924. This experiment also shows the effect of refraction from the normal to the plane, which means that \( n < 1 \) (where \( n = \text{index of refraction} \) and that there is a phase velocity inside the medium larger than \( c \), the speed of light in vacuum or air.

### 2.1 First Considerations and Applications of Total Reflection of X-rays

Some applications of the X-ray total reflection effect were suggested and performed immediately after the total reflection effect interpreted in terms of classical electrodynamics and Fresnel formalism had been used to calculate reflectivity and transmission intensities. Following the suggestions of E. Nähring, an idea was realized for use of the total reflection effect as a possible means of modifying the spectral distribution of primary radiation. The instruments so created were falsely named “total reflection monochromators” but did indeed suppress the high-energy part of the spectrum, thus filtering the short wavelengths of the continuum emitted by the X-ray tube. M. Montel (1956) reported and described this effect again. G. Damaschun et al. (1967) used this phenomenon to improve the monochromaticity of the primary beam, performing small angle X-ray scattering measurements with a Kratky camera.

Optical components for X-ray astronomy were designed using the total reflection effect and spectacular X-ray optical components were made to focus the X-ray beam into micrometer spots. This is achieved by arranging bent mirrors in one, two or more planes to produce a point focus from a source that originally emitted in a large solid angle. Another interesting application of the total reflection effect was direct measurement of the energy-dependent fluorescence signal, in particular characteristic X-rays from light elements in the range 180 (B) to 1024 eV (Na). This was performed using the reflectance of a mirror and the energy dependence of the critical angle of total reflection as dispersive element, in the early 1960s by H.K. Herglotz using a “paraffin mirror” for Be, B, C and a “LiF mirror” for N, O, F.

In 1954 L.G. Parrat published an excellent theoretical paper about the external total reflection of X-rays.
2.2 External Total Reflection

This phenomenon is observed if a fine narrow collimated X-ray beam impinges on the plane-polished smooth surface of any material. Normally, solid materials are used as mirrors but total reflection from liquid surfaces was also reported. The surface quality of a reflector is described well by mean roughness, which should be in the range of a few nanometers or less and an optical flatness of $\lambda/20$, where $\lambda$ is typically 589 nm in the visible light range.

Experimental observation of total reflection is best described by starting at large angles of several degrees of incidence, measured between the beam direction and the reflector surface. The X-ray beam having typically 5–20-keV energy (wavelength $\lambda$ from 0.24–0.06 nm) shows the normal behavior of penetration and absorption in the reflector. Looking in more detail, the beam inside the medium after penetration through the interface shows a slight angular deviation from its original direction to a smaller angle measured between the new direction of the beam and the plane of the interface. This refraction of the beam in the medium is the basis of the following conclusions. In decreasing the incidence angle a certain so-called critical angle is achieved where the direction of the propagation of the refracted beam is parallel to the surface of the reflector. Further reduction of the incidence angle leads to an intensive reflected beam having almost the same intensity as the incoming one. This is the totally reflected beam, where total refers to the almost identical number of photons in the reflected beam as in the primary beam. Figure 3 shows three different cases.

From theoretical considerations of Fresnel’s formalism it follows that even in the case of total reflection there is a certain amount of penetration of the primary X-rays into the reflector. This represents an energy transfer into the medium. The correlation between critical angle and the material constants as well as the energy of the impinging photons on the reflector is given by the physical parameters described by classical electrodynamics.

Starting with the complex index of refraction, $n$ which is given by its real and imaginary part, Equation (1)

$$n = 1 - \delta - i\beta$$

(1)

where the two terms $\beta$ and $\delta$ are described by the results of the classical electrodynamics of a dipole in the electric field of an incoming wave. The $\delta$ is often named the decrement of $n$ with small values in the $10^{-5}$ range; $\beta$ corresponds to the absorption term of the X-rays.

These values are correlated to the scattering factors $f_1$ and $f_2$ from Kramers Kronig dispersion relations which are tabulated by Henke et al.,(16) Equations (2) and (3)

$$\delta = Kf_1(E) = 4.15 \times 10^{-4} \frac{\rho}{AE} f_1(E)$$

(2)

$$\beta = Kf_2(E) = 4.15 \times 10^{-4} \frac{\rho}{AE} f_2(E)$$

(3)

where $\rho$ is the material density (g cm$^{-3}$), $A$ is the atomic weight, $E$ is the photon energy (keV) and $\mu$ is the mass absorption coefficient (cm$^2$ g$^{-1}$). $K$ is given by Equation (4)

$$K = \frac{r_0 \lambda^2}{2\pi} \frac{N_A}{A} \rho$$

(4)

with $\lambda$ as the wavelength of the incoming radiation, $r_0$ as the classical electron radius and $N_A$ as Avogadro’s number. $f_1$ approaches $Z$ (number of electrons) and shows only a discontinuity at the absorption edges and $f_2$ is proportional to the absorption coefficient.

The correlation between the critical angle $(\phi_c)$ and the index of refraction $(n)$ is derived assuming no absorption, i.e. $\beta = 0$ by Equations (5) and (6)

$$n = 1 - \delta = \frac{\cos \phi_c}{\cos 0}$$

(5)

$$1 - \delta^2 = 1 - 2\delta + \delta^2 = 1 - \sin^2 \phi_c$$

(6)

neglecting $\delta^2$ and approximating $\sin \phi_c = \phi_c$ which is valid for small angles, Equation (7) follows

$$\phi_c = \sqrt{2\delta}$$

(7)

Measuring the reflectivity $R$ which is defined as the ratio between the intensity of the incident beam versus the intensity of the reflected beam, curve $R$ versus angle shows a typical shape. The sharp decrease of $R$ at a certain angle defines the critical angle of total reflection. A remarkable observation is also the high value of $R$ below the critical angle which is close to unity (see Figure 4). The influence of parameter $\beta/\delta$ can also be seen. Higher absorption leads to a “smearing” of the step function at $\phi_c$. 

![Figure 3 Principle of total reflection, for three cases: $\phi > \phi_c$, $\phi = \phi_c$, $\phi < \phi_c$.]

Figure 4 Calculated reflectivity versus incident angle/critical angle of Si for various values of $\beta/\delta$. $\cdots$, $\beta/\delta = 0$; $\cdots$, $\beta/\delta = 0.0054$ (17.5 keV); $\cdots$, $\beta/\delta = 0.22$ (8 keV); $\cdots$, $\beta/\delta = 0.049$ (5.4 keV); $\cdots$, $\beta/\delta = 0.14$ (3 keV).

Figure 5 Penetration depth as a function of the ratio of incident angle to critical angle for Cu Kα radiation using a quartz reflector; 17.5 keV in Si.

Relating the behavior of the electromagnetic wave inside the medium to the associated damping effect, a term “penetration depth” can be defined which is the depth $z_p$ normal to the surface where the intensity of the incoming beam at the surface $z = 0$ is reduced to 1/e; a classical definition whenever absorption phenomena are described. Figure 5 shows the penetration depth as a function of the relative incidence angle for Mo Kα radiation.

3 TOTAL REFLECTION X-RAY FLUORESCENCE ANALYSIS

3.1 Historical Development

In 1971 Yoneda and Horiuchi(17) published a paper with the first experimental data from an EDXRF measurement using a Ge detector and excitation geometry in total reflection geometry from a sample of a dried spot of 100-ng Ni from an aqueous solution of NiCl$_2$ on an “optical flat”. In 1974 Aiginger and Wobrauschek(18) published results using a Si(Li) detector and a Suprasil reflector, where 5 µL of Cr salts in aqueous solution were dried and analyzed with a Cu-anode X-ray tube. A more detailed publication by Wobrauschek and Aiginger(19) appeared in 1975 showing theoretical considerations and details of the set-up, calibration curves, steps for the quantification and detection limits of 4 ng of Cr. In 1977 the GKSS group Knoth, Schwenke, Marten and Glauer(20) published the first prototype of a TXRF system and the analytical results of blood serum analysis. From that time on many more teams worldwide have been working on the development of this technique. In particular from 1986 there have been regular biannual meetings, TXRF workshops and conferences for the users of this young analytical technique.(21–25) In 1997 the first book dealing exclusively with TXRF, written by Klockenkämper, became available and gives an excellent summary of the principle, advantages and applications of TXRF.(26)

3.2 Total Reflection X-ray Fluorescence Analysis

Experimental Set-up

TXRF is basically an ED analysis with a special excitation geometry. In the standard case of EDXRF the angle between the primary incident radiation and the sample is 45°. In addition the detector is placed normal to the incident beam so that the angle between sample and detector is also 45°. The principle set-up is shown in Figure 6. A narrow almost parallel beam impingings at angles below the critical angle on the surface of the reflector which carries the sample as randomly distributed microcrystals in the center part of its surface. The X-rays scarcely penetrate the reflector and thus the contribution from scattered primary radiation from the substrate is minimized. The sample itself is excited by both the primary and the reflected beam so that the fluorescent signal is practically twice as intense as in the standard EDXRF excitation mode.

One of the differences between EDXRF and TXRF is the excitation geometry which is changed in such a way

Figure 6 Principle of TXRF; geometrical arrangement.
that the primary radiation impinges at an angle below the critical angle of total reflection on the surface of the reflector carrying the sample. The critical angles are in the range of a few milliradians for typical reflector materials like quartz or Si and primary radiation of 9.4 keV from a W-L or 17.5 keV from a Mo-anode X-ray tube.

With higher energies in the exciting spectrum, adjustments must be made for the proper incident angle below the critical angle which is given, corresponding to Equation (7), with the assumption that $f_i \approx Z$, and $Z/A \approx 1/2$ by Equation (8):

$$\phi_{\text{crit}} = \frac{20.7}{E} \sqrt{\rho}$$

where $\phi_{\text{crit}}$ is in mrad, $E$ in keV and $\rho$ in g cm$^{-3}$.

The main advantages of TXRF are:

1. The background caused by scattering of the primary radiation on the substrate is reduced.
2. The fluorescence intensity is doubled as the primary and reflected beams pass through the sample giving efficient excitation.
3. The distance between the sample on the reflector surface and the detector can be made small, thus the solid angle for detection is large.
4. All these advantages lead to lower limits of detection (LLD) compared to the standard EDXRF mode.

Depending on the X-ray source and the spectral modification devices, the LLD are in the “picogram” range for 2–3-kW standing anode X-ray tubes and in the “femtogram” range with SR.

4 SOURCES FOR TOTAL REFLECTION X-RAY FLUORESCENCE ANALYSIS AND SPECTRAL MODIFYING DEVICES

The excitation source used most in TXRF is a high-power diffraction X-ray tube with 2–3-kW applied where the line focus is taken. This type of X-ray tube is available with Cr, Cu, Mo, Ag and W anodes. For better excitation of light elements, Al or other special anode materials are chosen. The X-ray tubes need a power supply from an X-ray generator with high voltage heating for the filament and efficient water cooling. The line focus of the anode has to be used so that the brilliance emitted from that tube correlates with the slit-like collimator which is necessary to produce a narrow almost parallel beam with divergence less than the critical angles involved. A larger photon flux on the sample can be achieved technically by using rotating anodes made from Mo or W which can stand up to 18 kV. In all cases the focal size of the electron beam on the anode is a line of dimensions $0.4 \times (8 \text{ or } 12)$ mm. Emission of X-rays is observed at less than an angle of 6° to the anode surface, such that the optical focus is reduced by projection with sin 6° equal to 0.1–0.04-mm width.

The emitted spectrum is usually a continuum (white) with the highly intensive characteristic lines of the anode superimposed. In modern spectrometers the X-ray tube is usually operated with an applied voltage up to 40 or 60 kV. Photons with an energy of 40–60 keV are also available but not essential for excitation. An excellent tool for modifying the spectral distribution, in a way that suppresses the high-energy photons whereas lower energies including the intensive characteristic lines will be recorded, is the insertion of another reflector in the beam path. The energy dependence of the critical angle is used to achieve this effect. In adjusting for a fixed value for the angle, only photons up to a certain value of $E$ with respect to the angle are reflected. Those having more energy do not fulfill the reflection condition and are absorbed in the reflector material. This effect is comparable to a low-pass filter known from electronics. The reflected beam is of the same intensity as the primary beam but the high-energy photons are missing from its spectrum. These would cause an increase in the low-energy background due to Compton backscattering at the front side of the detector. If the higher energy photon is backscattered, the electron carrying the energy difference is scattered into the detector leading to an increased low-energy background. Thus complete suppression of the unwanted high-energy photons is achieved using a cut-off filter.\(^{(13,14,27)}\)

Another more effective way of modifying the exciting spectrum is by using a monochromator for the intensive characteristic primary radiation, e.g. Cr Kα, Cu Kα, W Lβ, Mo Kα. The most common are crystal monochromators, but they have the disadvantage of transmitting a very narrow energy band, in an electronvolt range smaller than the natural linewidth. The more efficient monochromators are layered synthetic microstructures.\(^{(28–30)}\) This multilayer (ML) is a perfectly polished flat substrate on the back of which a number of layer pairs with varying high Z and low Z material are sputtered. A few nanometers distance separates the layers and the system acts like a Bragg single crystal selecting a certain energy at a certain angle but with a larger $\Delta E/E$ and high reflectivity. Using such a device, the spectrum measured shows some extraordinary features. The background is practically zero in all regions except for the scattered primary energy. Only the fluorescence lines of interest are observed and detection limits with such an excitation mode are improved.

The excitation of elements is best if the photon energy of the exciting radiation is close to the individual
absorption edge. The search for anode materials for special applications has led to the development of an Al anode or a Si anode for analyzing all the elements below Si, such as F, Na, Mg and Al. The use of the L-lines of Rh or Mo for the light element excitation is also well known.

As there is a steady call for greater and greater improvements in detection limits, an approach has been applied using the most intensive source available at the moment, synchrotron radiation (SR), which has almost ideal features for TXRF. SR is produced by high-energy (GeV) relativistic electrons or positrons circulating in a storage ring. It is several orders of magnitude greater in brightness compared to X-ray tubes, has a natural collimation in the vertical plane and is linearly polarized in the plane of the orbit. The spectral distribution is continuous, so by proper monochromatization the performance of selective excitation under the best conditions is possible. Many applications can only be performed with SR and its combination with TXRF will be mentioned in the section on SR/TXRF. Experiments have been performed by several groups worldwide. The properties of SR are so challenging that much more effort should be made to develop accessibility to SR and in particular to beamlines in which a TXRF system can be installed.

The use of MLs or cut-off reflectors is not helpful if the task is to analyze high Z elements by their K shell emissions, which requires high-energy photons up to more than 120-keV energy. In this case a slit system of high Z elements will be taken to define the geometry of the beam.

All the possibilities for modifying the exciting beam are shown schematically in Figure 7. For further improvements in the spectral background, the scattering and absorption of primary photons in air should be avoided. Therefore the use of a vacuum chamber is recommended for optimized excitation conditions. The Ar K-line which is also excited in air will disappear from the spectrum and absorption of both primary and fluorescence photons is avoided. A background of low intensity is observed, and scattered primary X-rays still remain after interacting with the sample and the substrate, as do the characteristic lines from the reflector. If for any reason related to sample type or due to technological problems measurements in vacuum are not possible, improvements compared to measurements in air are achieved by flushing the chamber with He.

5 REFLECTOR SPECIFICATIONS: SURFACE QUALITY, MATERIAL, SHAPES

The presence of characteristic lines from the reflector material are sometimes disturbing especially if the analyte has the same elements. In this case the use of other materials is suggested and several materials have been tested. Quartz and synthetics like Synsil, Suprasil, fused silica and elemental Si are generally in use. The heavier elements like Ti, Nb, Ta have been tested and show excellent performance. Boron nitride, glassy carbon and the most simple types of perspex are light element reflectors that show no interfering characteristic lines. All geometric shapes are possible for reflectors, and typically a disk 3–4 mm thick, with a 30-mm diameter, is standard. The only important requirement is the surface quality, the mean roughness should be in the nanometer range. The overall flatness is given in terms of optical wavelength (589 nm), so typically λ/20 is sufficient for a good surface.

Requirements for the reflectors include:

- mechanical stability
- good machinability for grinding and polishing
- hard surface
- hyperpure material
- chemically resistive against acidic or chemically aggressive samples
- easy to clean for multiple use
- XRF lines of the reflector not in the energy range of interest
- an economic price; the perspex reflector is a few cents, whereas the polished Synsil reflector is about 40 US$.

6 TECHNICAL INSTRUMENTATION FOR TOTAL REFLECTION X-RAY FLUORESCENCE ANALYSIS

The complete TXRF experimental set-up with the various components is seen in Figure 8. Technically all
Figure 8 Set-up of a TXRF unit with possible components.

components need to be adjusted by translation and rotation stages and tilters to obtain perfect alignment with the X-ray beam and the total reflection condition. These motions can be mechanically adjusted by hand or remotely by controllers. Another possibility is to use a firm prealigned module with all components fixed, where the only movable part is the sample changer. To observe the effect of total reflection several units can be used as specified in Figure 8. The modern way is the charge coupled device (CCD) camera where the X-rays fall directly on the chip and induce an image where the pixels are hit. This is made visible by a monitor in the normal way. The ZnS screen can be used to watch the X-rays either by eye or again via a CCD camera and lens focused on the screen. Because part of the direct beam passing above the surface of the reflector can be observed, the image for proper alignment is always a double beam – the primary and the reflected one separated according to the adjusted angle. Knowing the distance between the reflector and the screen, one can then calculate the angle adjusted.

To demonstrate the advantages of TXRF in a realistic comparison between the same sample measured in standard EDXRF geometry and TXRF set-up, the spectrum of a reference standard water 1634a from NIST (National Institute of Standards and Technology) is shown in Figure 9. The spectrum in Figure 9(a) was measured by putting a droplet of 10 µL on a Kapton foil (8 µm), drying the sample and inserting it with a spectrocup into a standard EDXRF spectrometer with a Rh tube operated at 40 kV and 0.35 mA, leading to 65% deadtime under vacuum conditions, which were found to be the optimal conditions. Also 10 µL of the sample was dried on a quartz reflector and inserted in the TXRF spectrometer equipped with a Mo tube, a ML monochromator and a vacuum chamber (40 kV, 50 mA) to obtain the spectrum shown in Figure 9(b). Optimized conditions were applied in both cases for a fair comparison. The lower detection limits and the determination of elements which were not seen in standard EDXRF but clearly in TXRF, demonstrate the analytical power of the method.

To demonstrate the development of the method over time and the improvements in the detection limits achieved with TXRF, the following data for the detection limits are given. In 1975 LLDs were in the nanogram range, but by 1985 improvements in spectral modification, excitation geometry and detection systems led to LLDs in the picogram range. Using SR, in 1995 LLDs at femtogram levels were achieved.

1975 1985 1995
nanograms picograms femtograms

These values are extrapolated values, obtained from interference-free single-element standard solutions. All the figures were calculated from the accepted definition of detection limits for spectrometric methods recommended by IUPAC (International Union of Pure and Applied Chemistry), expressed by the simple relation, Equation (9), between background and sensitivity

\[
\text{LLD} = \frac{3}{S} \sqrt{\frac{t}{T_b}}
\]

where \( S \) is the sensitivity in counts per second of the respective net signal divided by the mass or concentration
of the element present, $I_B$ is the background intensity and $t$ the measuring time in seconds.

### 7 DETECTORS AND ELECTRONICS

The detectors used in TXRF are semiconductor detectors. The lithium drifted silicon (Si(Li)) detector, the hyperpure germanium (GeHP) and from older days the lithium drifted Ge (Ge(Li)) detectors are used. Their main advantages are compact size, nonmoving system components, and excellent energy resolution, where the best have 120 eV at 5.9 keV. Because of their operation principles, these detectors have an inherent simultaneous multielement capacity, which leads to a short measuring time for all elements as the detectors select the energy and collect counts at the same time. Some disadvantages include the need for liquid nitrogen (LN) cooling during operation, the necessity of having a very thin 8–25 µm sensitive Be window and the fact that the maximum processable number of counts is limited to about 40 000 cps. This figure can be increased to 100 000 cps, but with loss of the excellent performance data. The operation principle is as follows. The detector is a disk of very pure Si or Ge with dimensions of 4–10-mm diameter and 3–5-mm thickness. Even careful production of the Si ingot where this disk is cut will have some trace impurities. To compensate and bind all free electrons, lithium ions drift in the silicon crystal to neutralize the Si crystal defects in a particular zone, the so-called intrinsic zone. Au contacts are evaporated and a reverse voltage applied. To keep the leakage current as low as possible the crystal is cooled with LN, so that the detector has to be operated in vacuum and the radiation to be measured has to pass a thin entrance window, usually Be.

Applying a reverse voltage in the charge carrier free intrinsic zone, an absorbed X-ray photon is converted into charge by ionization. In the Si crystal, electron–hole pairs are created and their number is the ratio between the energy of the absorbed photon and the energy required to create one electron–hole pair. The electrons and holes are quickly swept to the contact layers by the electric field created by the applied reverse bias on the crystal.

Figure 10 shows the operation principle schematically. The charge induces a signal at the gate of the cooled field effect transistor (FET) which is the input stage of the charge sensitive preamplifier. The output signal is fed to a pulse processor which shapes the pulse and amplifies it further. This signal is in the range up to 10 V and is proportional to the energy of the absorbed photon. The signal is stored digitally, so the analog-to-digital converter (ADC) prepares the digitized signal. Finally all signals are stored in a multichannel analyzer (MCA) where the event is stored according to the digitized number in that channel.

---

**Figure 9** Comparison of a sample (10 µL of NIST water SRM 1634) analyzed by standard EDXRF (Rh low-power tube, dried on Kapton 8 µm) (a) and TXRF (ML monochromatized Mo tube, vacuum chamber) (b).

**Figure 10** Scheme of the working principle of a Si(Li) detector.
For K shell radiation from high Z elements, offering high transmission for low-energy radiation. To pass, new window materials have to be used in the range 100–1000 eV. Be windows would not allow photons. The elements of interest are emitting low- or high-energy photons in all the layers between the incoming photon and the sensitive volume. The layers are: Be window, gold contact layer and dead layer of the p-type Si material. On the high-energy side the absorption of the high-energy photons in the detector material itself is reduced (lower mass absorption coefficient) and fewer pulses result. From the efficiency it can be seen that for the low- and the high-energy side some precautions have to be made if the elements of interest are emitting low- or high-energy photons.

A typical calculated efficiency curve versus energy is shown in Figure 11. The reason for the decrease in efficiency for low-energy photons is the absorption of the photons in all the layers between the incoming photon and the sensitive volume. The layers are: Be window, gold contact layer and dead layer of the p-type Si material. On the high-energy side the absorption of the high-energy photons in the detector material itself is reduced (lower mass absorption coefficient) and fewer pulses result. From the efficiency it can be seen that for the low- and the high-energy side some precautions have to be made if the elements of interest are emitting low- or high-energy photons.

The light elements emit fluorescence radiation in the range 100–1000 eV. Be windows would not allow them to pass, so new window materials have to be used offering high transmission for low-energy radiation. For K shell radiation from high Z elements a better absorbing material is needed, like germanium. A high-quality detector offers high energy resolution (low fwhm), a high efficiency, symmetric peak shape, and a small detector contribution to peak and background, leading to a high peak to background ratio. The background is influenced by the detector quality as well as by the source sample interactions. Incomplete charge collection at the electrodes leads to low-energy tailing of the peak and a higher remaining background. Additionally the escape effect creates escape peaks and thus an increased background. This escape effect occurs in the outer zones of the crystal where the incoming photon is absorbed close to the surface of the crystal. If the energy is high enough the crystal material itself is excited to emit its own fluorescence Si K or Ge K or L lines. From the near surface these fluorescence photons can escape and do not contribute to the charge carrier production. This causes an additional line in the spectrum, called an escape line, which is shifted in energy just by the value of the energy of the characteristic Si or Ge radiation. Overlap with fluorescence lines can occur and has to be kept in mind. Nevertheless the software for the spectral deconvolution of the measured peaks is so sophisticated that accurate interpretation is possible. Another inherent advantage of semiconductor detectors is the possibility of bringing the detector crystal very close to the sample. Assuming that the crystal is 3–4 mm behind the Be window and a 1-mm distance from sample to entrance window was chosen, this leads to a total distance of 5 mm which gives rise to a large solid angle. The physically largest component of the detector is the storage tank for LN. This Dewar has a storage capacity from 5 to 30 L. The system inside must be under vacuum, so a housing “snout” is kept around the crystal, shielding it from the outside environment. The modern detector can be mounted in any position, vertical, horizontal and inclined because the Dewar has a special filling and venting system.

Two recent developments show an interesting approach to improving two problematic features of the ED detector. LN filling can be a problem if there is no delivery or production. The detector, with the exception of Ge(Li) types, can warm up. The use of Peltier-cooled detectors is a step in the direction of independence of the LN supply. A new generation of ED detectors with a Si PIN diode and Peltier cooling are resulting in lightweight hand-sized units with acceptable resolution of 160–200 eV. Another development is in cryogenic detector technology, a superconducting tunnel junction operating at a few millikelvin to achieve energy resolution of 10 eV at 5900 eV. Another group uses the idea of a microcalorimeter where the temperature change created by the absorbed photon is measured. These developments are in progress and can provide a big step forward for specific applications.

The signal from the preamplifier has to be pulse shaped and amplified. This is done by electronic units.
8 QUANTIFICATION IN TOTAL REFLECTION X-RAY FLUORESCENCE ANALYSIS

In XRF the intensity of the fluorescence radiation depends on the following parameters, Equation (10)

\[
I(E_{K\alpha}^i) = \int_{E_{E_{max}}^{E_{abs}}} I_{0}(E)G_{1}\frac{\tau_{K}^{i}(E)}{\rho}w_{k}p_{0}^{i}c^{i}V^{i}(E)
\times \exp\left(\frac{\mu(E)}{\rho \sin \psi} + \frac{\mu(E_{K\alpha}^{i})}{\rho \sin \psi}\right) \rho d
\times G_{2f}(E_{K\alpha}^{i})\varphi(E_{K\alpha}^{i})dE
\]

where \( i \) is the index of the respective element, \( E_{abs} \) is the energy of the absorption edge of element \( i \), \( E_{max} \) is the maximum energy of the excitation spectrum, \( d \) is the thickness of the sample perpendicular to the sample surface, \( E_{K\alpha} \) is the energy of the \( K\alpha \)-radiation of element \( i \), \( I_{0}(E)dE \) is the spectral distribution of the exciting radiation, \( x \) is the depth of the inspected layer perpendicular to the sample surface, \( \delta \) is the thickness of the inspected layer, \( G_{1}, G_{2} \) are geometry factors, \( \rho \) is the density of the sample, \( \psi \) is the take-off angle of the exciting radiation, \( \varphi \) is the fluorescence yield of the \( K\alpha \)-line, \( \rho a \) is the emission probability of the \( K\alpha \)-line, \( c \) is the concentration, \( V(E) \) is a factor, taking secondary excitation into account, \( f(K\alpha) \) is the absorption of the fluorescence radiation between sample and detector and \( \varepsilon(K\alpha) \) is the detector efficiency.

After integration of Equation (10) for \( x \) the absorption term \( A \) can be defined by Equation (11):

\[
A(E) = \frac{1 - \exp\left(\frac{\mu(E)}{\rho \sin \psi} + \frac{\mu(E_{K\alpha}^{i})}{\rho \sin \psi}\right)}{\rho d}
\]

Terms depending only on physical properties of the atoms are called fundamental parameters. \( \sigma \) is the fluorescence cross-section and is tabulated for various excitation energies and elements, Equation (12)

\[
\sigma_{K\alpha}^{i}(E) = \frac{\tau_{K}^{i}(E)}{\rho}w_{k}p_{0}
\]

Therefore, dealing with low concentrations where the factor \( V(E) = 1 \), Equation (10) can be written by Equation (13)

\[
I(E_{K\alpha}^{i}) = \int_{E_{E_{max}}^{E_{abs}}} I_{0}(E)G_{1}\frac{\rho d}{\sin \psi}\sigma_{K\alpha}^{i}(E)c^{i}A(E)
\]

\[
\times G_{2f}(E_{K\alpha}^{i})\varphi(E_{K\alpha}^{i})dE
\]

Theoretically it is possible to perform a quantitative analysis with Equation (13) without standard samples, but several problems have to be considered. The mass absorption coefficient of the sample \( \mu(E)/\rho \) is determined by the composition of the sample, a summation about all elements in the sample is necessary. Thus an iterative procedure has to be applied for a solution. A further problem is knowledge of the spectral distribution of the exciting radiation.

Assuming a monochromatic beam, the integral of Equation (13) can be removed and all parameters depending on the energy of the exciting radiation, like \( \sigma_{K\alpha}^{i}(E) \equiv \sigma_{K\alpha}^{i}(E_{0}) \), \( A(E) \equiv A(E_{0}, E_{K\alpha}^{i}) \) become more
simple, if \( E \) is substituted by the monochromatic excitation energy \( E_0 \).

\[
I(E_{Ko}) = I_0(E_0)G_1\frac{\rho}{\sin\psi}\sigma_{Ko}^f(E_0)c^f\gamma(E_0)G_2f(E_{Ko})\varepsilon(E_{Ko})
\]

(14)

If the sample is very thin, \( (x \rightarrow 0) \), the integration in Equation (14) becomes \( \lim_{x \rightarrow 0} \frac{1}{x^2} = 1 \). Absorption can be neglected, as well as secondary enhancement. The intensity of the fluorescence radiation is then given by Equation (15)

\[
I(E_{Ko}) = \int_{E=E_{min}}^{E=E_{max}} I_0(E)G_1\frac{\rho d}{\sin\psi}\sigma_{Ko}^f(E)c^fG_2f(E_{Ko})\varepsilon(E_{Ko}) \, dE
\]

(15)

with \( (\rho d) \) as the areal mass density of the sample \( (\rho d = m/F) \).

In this special case the relation between concentration and fluorescence intensity is linear. The so-called sensitivity (cps/sample mass) can be defined, Equation (16):

\[
S_i = \frac{I_i}{c_i m}
\]

(16)

\( S \) depends only on fundamental parameters and the measuring conditions, which can be assumed to be constant in a spectrometer or an experimental set-up. Thus the relative sensitivities (sensitivity factors) of various elements \( i \) referring to the intensity of a standard element \( I^i \) (internal standard) can be determined, Equation (17):

\[
S_{rel}^i = \frac{I_i}{I^i} = \frac{\int_{E=E_{min}}^{E=E_{max}} I_0(E)\sigma_{Ko}^f(E)c^fG_2f(E_{Ko})\varepsilon(E_{Ko}) \, dE}{\int_{E=E_{min}}^{E=E_{max}} I_0(E)\sigma_{Ko}^f(E)c^fG_2f(E_{Ko})\varepsilon(E_{Ko}) \, dE}
\]

(17)

with \( s \) being the index for the internal standard element.

This definition is valid for the same concentration of the element \( i \) and the internal standard element. Relative sensitivities can be determined experimentally with standard samples or calculated theoretically if all parameters are known (thin film approximation, monoenergetic excitation, detection efficiency = 1). Owing to the ratio, all geometry factors cancel.

The determination of the concentration \( c^i \) of an unknown element in a sample spiked with an internal standard \( s \) is simple, if relative sensitivities \( S_{rel}^i \) are determined, Equation (18)

\[
c^i = \frac{I_i}{I^i} \frac{1}{S_{rel}^i} c^s
\]

(18)

One of the inherent advantages in TXRF is that the sample can be assumed to be thin, so the simple conversion of fluorescent intensities \( I \) into concentration data \( c \) is valid, as there is a linear correlation between intensity \( I \) and concentration \( c \). After establishing a calibration curve either from known multielement standards or by using the fundamental parameters to calculate the calibration curve theoretically, the conversion of \( I \) into \( c \) can be performed immediately. The addition of one element as internal standard of known concentration to the sample improves the accuracy of the results, because geometric and volumetric errors will cancel out and the inhomogeneous excitation caused by the standing wave field above the reflecting surface vanishes.

Figure 12 shows the linear calibration curves with respect to Se as internal standard for Fe, Zn and Sr, obtained from standard solutions, from which the relative sensitivity can be determined. Figure 13 shows

![Figure 12](image)

**Figure 12** Calibration curve of Fe, Zn and Sr relative to Se as internal standard. \( I(Fe Ko)/I(Se Ko); \quad I(Zn Ko)/I(Se Ko); \quad I(Sr Ko)/I(Se Ko); \quad I(Fe Ko)/I(Fe Ko); \quad I(Zn Ko)/I(Zn Ko); \quad I(Sr Ko)/I(Sr Ko).**

![Figure 13](image)

**Figure 13** Measured and extrapolated relative sensitivities versus atomic number.
the relative sensitivities versus atomic number and a fitted curve through the data points allowing interpolation of measured data for elements not measured. To calibrate the spectrometer it is necessary to determine the relative sensitivities once. Then any unknown sample can be easily quantified after adding the respective internal standard.

A sample is “thin” if the thickness does not exceed the critical thickness \( d_{\text{max}} \) calculated by Equation (19)

\[
d_{\text{max}} = \frac{0.05/\rho_{\text{matrix}}}{(\mu/\rho)_{\text{sample}}} \tag{19}
\]

This is about 4 \( \mu \)m for organic tissue, 0.7 \( \mu \)m for mineral powder and 0.01 \( \mu \)m for metallic smears, following Klockenkämper. However, on the assumption that the matrix absorption for the analyte differs only slightly from that of the internal standard, these critical thicknesses are much greater.

9 SAMPLE PREPARATION

The preparation of the sample is a very important factor influencing the achievement of satisfying detection limits. Generally Figure 14 shows the various common

![Sample preparation methods](https://example.com/sample-preparation-diagram)

Figure 14 Sample preparation methods for TXRF. PTFE, polytetrafluoroethylene; NADDTC, Na-diethyldithiocarbamate; APDC, ammonium pyrrolidinedithiocarbamate; DBDTC, dibenzylthiocarbamate.

and applied methods of sample preparation in TXRF depending on the kind of sample to be analyzed. One of the big advantages of TXRF is the small sample volume required for analysis, only a few nanograms of sample mass or a few microliters of sample volume are required. This is in contrast to other sensitive analytical methods for trace analysis and in some cases is a great advantage.

First of all the sample must be representative of the whole specimen, therefore homogenization is required. The easiest way is the direct analysis of liquid samples. A few microliters (of the sample solution mixed with the internal standard) are pipetted on to the sample reflector and dried, either in a desiccator or with infrared light or on a hot plate. Depending on the matrix of the sample, this matrix should be digested to eliminate the low Z elements like C and O. As an alternative, solid samples can be crushed and then ground to a fine powder of micrometer grain size. This powder can be mixed with a liquid to produce a suspension which can be pipetted, after adding an internal standard, on to the sample reflector. The pulverized sample can also be dissolved in a suitable solvent and after adding the internal standard an aliquot is pipetted on to the sample reflector and dried.

Various methods for decomposing biological and environmental materials are used. Biomaterial can be decomposed using a low-temperature oxygen plasma asher. The ash can then be dissolved in acid. The most popular method for decomposing biological and environmental samples like plants, tissues, and sediments is wet digestion in Teflon® vessels (Teflon bombs). It is possible to use the open or closed version with high pressure or without. Strong acids like HNO₃, HF (needed to decompose sediments and rocks), HNO₃ + HCl or HNO₃ + H₂O₂ in different proportions are mostly used. HF can be used only at low concentrations if quartz glass reflectors are used, because this acid attacks them. The use of microwaves often reduces the time of digestion to less than 1 h. Extraction of traces of organic phases or reverse phase chromatography can also be used for preconcentration of the traces.

Freeze drying is a method of reducing the volume of a solution or any sample containing water. The sample is frozen and water is evaporated under vacuum conditions. The dried residue can be dissolved in small volume of acid or wet digested. It is also possible to extract traces of certain elements by phase separation. An organic solvent is added to a given volume of sample in an aqueous solution, which has an appropriate pH and is spiked with an internal standard, and mixed thoroughly. Then the two phases are separated. Traces of the metal ions stay in the organic phase, while the matrix elements are left in inorganic solutions. The organic liquid can be directly pipetted on to the reflector. The separation of traces by

</table>
adding a chelating agent and precipitating the metal ions is another commonly used technique. The metal complexes are filtered through a membrane filter and dissolved in a suitable organic solvent.

Generally loss of elements and contamination by other elements can occur during sample preparation.

Pigments from oil paints can be sampled by using a cotton bud. A few nanograms of material are rubbed from the painting and deposited via the cotton bud onto the sample reflector. Aerosols can be directly collected on sample carriers, used as an impaction stage. Individual particles can simply be put directly on the sample carrier. Solid samples can also be rubbed on the reflector; a small amount of sample material is smeared on the carrier. Biomaterial can be freeze-cut by a microtome and the frozen section placed on the reflector.

For surface and thin layer analysis, the sample has to offer a smooth polished Si surface and can be analyzed directly. A very common preconcentration technique used for the analysis of Si-wafer surfaces is the VPD (vapor phase decomposition) technique. The wafer is exposed to HF vapor, leading to dissolution of the SiO₂ surface layer of the wafer. The impurities can then be collected by scanning the surface systematically with a droplet of a special liquid or water. This integrates the impurities of the complete surface in the droplet, which can then be dried and measured by TXRF.

Generally the sample preparation method has a tremendous influence on the detection limits that can be obtained, documented in Table 1.

Details of sample preparation procedures can be found in Prange and Schwenke, Holynska et al., and Dargie et al. (35, 36, 37)

## 10 APPLICATIONS

TXRF allows the simultaneous determination of trace elements in samples of small volume. The three advantages, namely multielement capability, LLD and small sample volume required characterize the analytical capacity of TXRF. The additional advantages of insensitivity to matrix effects, easy calibration, fast analysis and low costs lead to almost unlimited applications. Table 2 gives an overview of various kinds of samples already analyzed with TXRF.

Generally all kinds of aqueous or acidic liquids (where the liquid matrix is evaporated) and also solids, can be analyzed, a small amount being deposited on a sample reflector. Oils, alcohols, whole blood and blood serum can be analyzed after special treatment.

### 10.1 Environmental Samples

The almost optimal sample for TXRF is the water sample. Pure water like rain or tap water can be analyzed directly. River water or seawater, as well as wastewater, require sample preparation to remove suspended matter or the salt content. Figure 15 from Klockenkämper shows the spectrum of a rainwater sample with Ga added as internal standard. 10–100 μL.

TOTAL REFLECTION X-RAY FLUORESCENCE

10.3.1 Analysis of Wafer Surfaces

The real breakthrough in industrial TXRF applications came, when it was discovered that optically flat, polished wafer disks, made from pure Si are suitable for investigation with TXRF. In order to remain competitive, the semiconductor industry is being constantly forced to increase the performance and reduce the cost of integrated circuits (ICs) by shrinking device dimensions and increasing the number of devices per unit area on IC chips. Strong correlations have been found between the presence of metal contamination on the wafer surface and process yields. Even very low concentrations of atomically dispersed metals can create atomic scale defects which lead to leakage of current, gate insulator breakdown, or poor threshold voltage control. All of these can result in device failure or reliability problems. Examples of metals which can cause degradation include Na, Al, Ca, Fe, Ni, Cu and Zn. In decreasing the size of devices the acceptable level of metal contamination decreases as parts of the matrix. Detection limits are in the range of 5–20 ng mL^{-1}. Low-temperature plasma ashing is also suitable; the residue has to be dissolved by HNO₃.

10.2 Medical Applications

There is an extensive interest in trace element determination in the medical field, because either depletion or accumulation of trace elements can effect the biological functions of human beings. Whole blood and blood serum, amniotic fluid, organ tissue, hair and dental plaque were analyzed. Detection limits down to 20 ng mL^{-1} for body fluids after microwave digestion and 10 ng g^{-1} for freeze cutting were reported. A small piece of tissue is frozen and then cut by a microtome in thin sections of about 15-µm thickness. The section is then placed on a sample reflector and spiked with an internal standard. This method was applied to tissue of kidney, liver and lung.

10.3 Industrial Applications

Quality control is performed by analyzing ultrapure reagents, like acids, bases and solvents. High-purity metals like aluminum, iron or silicon can also be measured after appropriate matrix separation.

Another field is the analysis of mineral and synthetic oils. Crude oils, lubricating oils, motor oils and diesel fuel have been analyzed. Light oils can be diluted with chloroform or toluene, the volatile matrix then removed by evaporation, and detection limits of micrograms per milliliter are achieved. If detection limits of nanograms per milliliter are required, low-temperature oxygen plasma ashing is necessary.

are required and dried on a clean sample reflector. Detection limits are in the low nanogram per milliliter range. To reduce the detection limits down to the 10 pg mL^{-1} level, freeze-drying with additional leaching of the residue with HNO₃ have to be applied. To remove the salt matrix from seawater, complexation, chromatographic adsorption and subsequent elution have to be performed. This method was developed by Prange et al. Suspended matter separated from filtrates can be analyzed by digesting the filter with HNO₃. For the analysis of sediments microwave digestion is recommended.

Aerosols can be analyzed by collecting on a filter and digesting the loaded filter material, or more conveniently, by direct sampling on the sample reflector, deposited in an impactor stage. Plexiglas (Perspex) carriers can be used. If the collected air is wet, the aerosols are reliably deposited on the carrier; if the air is dry, they can be bounced off. This can be prevented by coating the reflectors with a thin film of suitable grease. The reflectors loaded with collected aerosols can be directly analyzed after adding an internal standard. Detection limits are in the range of 0.1 ng for 1 h collection time and a sampling volume of 0.5 m³. Owing to direct analysis systematic errors due to digestion are avoided.

Environmental monitoring can be done by analyzing appropriate plants like moss or lichen (biomonitoring). All individual components of plants can be analyzed after sample preparation. After cleaning, shredding, freeze-drying and finally pulverizing, the powder is mixed with HNO₃ and digested in a Teflon bomb.

It is recommended that vegetable oil be diluted with toluene and an oil-based standard should be added as internal standard. After pipetting an aliquot on the sample reflector, it is heated up to evaporate the volatile matrix. Counts × 1000...

Figure 15 Typical TXRF spectrum of rainwater sample with 60 ppb Ga added as internal standard. (Reproduced by permission of John Wiley & Sons from Klockenkämper.)
The ability to measure low levels of contamination is crucial for developing techniques to remove these contaminations. The Semiconductor Industry Association (SIA) 1997 National Technology Roadmap for Semiconductors (NTRS) projects that the required sensitivities for transition metals will be at $3 \times 10^8$ atoms cm$^{-2}$ in the year 2001. At the moment (1999) $10^9$ atoms cm$^{-2}$ level is reached by conventional TXRF using standard tube excitation (Atomika TXRF8030W, http://www.atomika.com) or rotating anode tube excitation (Philips TREX 630 T/S, http://www.analytical.philips.com; Rigaku 3750 TXRF).

The advantage of measuring the surface contamination with TXRF is that the wafer can be mapped by moving the wafer in the plane below the detector to obtain contamination information from each point of the wafer. The inspected area is determined by the detector aperture and detector crystal size. Spatially resolved analysis is completely nondestructive and can be performed “in-fab”, close to the point of fabrication. Figure 16 from Berneike shows a wafer mapping for S, Br, Fe and Ca. It can be seen, that the spatial distribution of contamination is different for different elements.

If the wafer is treated with VPD (see section 9 on Sample Preparation), all impurities of the oxide layer of the whole wafer surface are collected in one drop, leading to a detection capability of $10^6$ atoms cm$^{-2}$, but losing the advantage of local information as well as nondestructiveness.

To measure surface contamination on wafers a special set-up is required, allowing measurement of the wafer without any surface contact and with the possibility of an angle scan. Measuring the angle dependence of the fluorescence signal allows the form of the contamination, film-type or particulate-type to be distinguished (see section 11 on Characterization of Near Surface Layers). From this kind of measurement it is also possible to check whether the signal comes from surface contamination or whether the atoms are below the surface.

### 10.3.2 Analysis of Thin Layers

Measuring the angle dependence of the fluorescence signal allows analysis of single or MLs on smooth substrates like wafers. Composition, density and thickness can be determined. Figure 17 from Weisbrod et al. shows an example of a bilayer system, the first layer consists of a Cr–Fe–Ni alloy, the second layer of Pd being followed by a Si wafer substrate. From the measured angle profile the thickness of the alloy layer was determined.

---

Figure 17 Fluorescence signal versus angle of incidence for a two-layer system on a Si wafer; the best fit was found for: Ni: 23.8%, Fe: 29.5%, Cr: 46.7%, $\rho = 7.0 \text{ g cm}^{-3}$, $d = 5.9$ nm for the alloy layer and $\rho = 11.2 \text{ g cm}^{-3}$, $d = 257$ nm for the Pd layer. (Reprinted from Weisbrod et al.,$^{59}$ Copyright (1991) with permission from Springer-Verlag.)

to be 5.9 nm (C(Cr) = 46.7%, C(Fe) = 29.5%, C(Ni) = 23.8%) with $\rho = 7 \text{ g cm}^{-3}$, a thickness of 257 nm and a density of 11.2 g cm$^{-3}$ were determined for the Pd layer.

10.4 Forensic and Art Historical Applications

For forensic applications the microanalytical capability of TXRF is the outstanding feature. In this field, microsamples are very common. Specific problems have been investigated, like hair samples, glass particles, tape fragments, drug powder, semen traces, gun-shot residues and textile fibers.$^{60,61}$

Another application relating to the microanalytical capabilities of TXRF is the investigation of art objects. Favorable results include dating of objects and identification of fakes. Oil paintings have been investigated by analyzing the pigments, which are characterized by a limited number of major elements. Cotton buds can be used to remove an amount of about $1 \mu\text{g}$ from the paint before depositing it on a sample reflector.$^{62}$

11 CHARACTERIZATION OF NEAR SURFACE LAYERS

An application of TXRF that is gaining importance is the nondestructive element analysis of near surface layers: layers on top of a reflecting surface as well as so-called “buried” layers below a reflecting surface. This is a consequence of the variation in the primary intensity with the angle of incidence above and below the surface. The variation results from interference caused by the superposition of incoming and reflected beams, as can be seen in Figure 18 from Klockenkämper, p. 55$^{26}$ for Si and Mo Kα radiation. A standing wave is formed above the surface. At a critical angle $0.1^\circ$ (1 mrad), nodes and antinodes follow at an interval of about $d = 18$ nm and the first antinode coincides with the surface. Assuming a reflectivity of 80%, the nodes have a 3.6-fold intensity of the primary beam. Below the surface the intensity is damped exponentially within a depth of some 10 nm (penetration depth). For angles smaller than the critical angle, the distance $d$ is stretched and the first antinode moves away from the surface. Inside the substrate, the intensity is damped within a few nanometers. For angles larger than the critical angle, $d$ is compressed, the oscillations vanish and the intensity approaches unity; also inside the substrate, the penetration depth increases to a few micrometers.

As the primary field varies with the angle of incidence, so the intensity of the fluorescence signal also shows this variation. From the shape obtained it is possible to distinguish between film-type samples, residue samples, thin layers and buried layers. The theory is discussed in detail by Knoth et al.$^{63-69}$ and De Boer et al.$^{70-73}$ as
well as by Klockenkämper.\textsuperscript{(26)} Figure 19 from Weisbrod et al.\textsuperscript{(64)} shows the differences. In the case of residue on a surface (droplet pipetted on reflector, liquid removed), the signal is proportional to the factor $1 + R$, where $R$ is the reflectivity. This is only valid if the grain size of the residue is in the range of 100 nm, because the oscillations vanish. Therefore the addition of a homogeneously distributed internal standard is necessary for calibration. If the reflectivity is assumed to be nearly unity, the fluorescence signal is doubled for angles less than the critical angle. There is angle dependence of the bulk signal for atoms exceeding a few 1000 nm depth; the signal is low for small angles and increases rapidly above the critical angle due to an increase in the penetration depth. For the near surface impurities the angle dependence leads to a strong peaking at the critical angle. Looking at an analyte below the surface, so-called “buried” layers, the fluorescence signal demonstrates a behavior like that shown in Figure 20, taken from Klockenkämper.\textsuperscript{(26)} A rectangular profile of Co atoms in Si is assumed for depths varying from 1 to 1000 nm. Reflecting layers on a substrate induce some oscillations due to the standing waves. Figure 21, taken from Klockenkämper,\textsuperscript{(26)} shows various Co layers on Si excited by Mo Kα radiation. The critical angle changes from that of Si to that of Co

Figure 18 Primary intensity above and below a thick Si substrate, Mo Kα energy, various angles of incidence: $0.05^\circ$ (---), $0.1^\circ$ critical angle (-----) and $0.2^\circ$ (----). (Reproduced by permission of John Wiley & Sons from Klockenkämper.)

Figure 19 Characteristic shape of the angular dependence of the fluorescence signal versus angle of incidence for three cases of analyte locations: residue on the surface, surface layer (analyte near surface) and homogeneous bulk. (Reprinted from Weisbrod et al.,\textsuperscript{(64)} Copyright (1991) with permission from Springer-Verlag.)

Figure 20 Angle dependent fluorescence signal from analyte atoms buried in a thick Si substrate. Mo Kα was the energy of the exciting radiation, the depth was varied but a constant area density was assumed. (Reproduced by permission of John Wiley & Sons from Klockenkämper.\textsuperscript{(26)})
Figure 21 Angle dependent fluorescence signal emitted from Co-layers on a Si substrate with various layer thickness (in nm) and Mo Kα as exciting radiation. The maximum for the ultrathin layers is located at the critical angle of Si (dashed vertical line), and is shifted to the critical angle of Co (dotted vertical line) if the layer is more then 10 nm thick. (Reproduced by permission of John Wiley & Sons from Klockenkämper.26/)

with increasing Co thickness. Comparing the shape of the angle dependence signal for near surface layers below and above, no difference caused by the continuity condition is apparent, which is also seen in Figure 19: the primary field is nearly the same just above and just below the surface.

Thus it is possible to determine the location of analytes, the composition, the density and the layer thickness or the implantation depth. Multiple layered samples can also be analyzed.

12 SYNCHROTRON RADIATION EXCITED TOTAL REFLECTION X-RAY FLUORESCENCE ANALYSIS

It can easily be seen from Equation (9) that there are different ways of improving the detection limits, namely increasing the sensitivity $S$, reducing the background and increasing the measuring time, which, however, is limited for practical reasons.

One way to reduce the spectral background is to use total reflection geometry. A further possibility for reducing the background is the use of polarized primary radiation.74,75 A scheme is shown in Figure 22.

Owing to the anisotropic emission characteristics of the scattered radiation based on classical dipole radiation, it is advantageous to place a detector in such a position that only the isotropic emission of the fluorescence signal is detected. Thus the combination of TXRF with polarized radiation leads to a lower background. Moreover, the use of monochromatic primary radiation improves the background conditions because only photons with one energy can be scattered. An increase in sensitivity can be attained by using a tunable intense excitation source, enabling the exciting energy to be adjusted to just above the absorption edge of the element of interest.

SR with its outstanding properties offers new possibilities for improving the power of TXRF. The intense beam with a continuous spectral distribution from infrared to high-energy photons, as well as the linear polarization in the orbit plane and its natural collimation, are features best suited for excitation in total reflection geometry. Figure 23 shows the spectral brightness of Beamline L at HASYLAB, allowing excitation by photons between a few electronvolts and a few hundred kiloelectronvolts. For optimal excitation conditions the spectral distribution can be modified by elements like cut-off mirrors, monochromators and filters. Details can be found in Wobrauschek and Streli.76

ML monochromators are best suited for combination with SR excited XRF.77 In comparison with crystal monochromators they offer a larger bandwidth ($\Delta E/E \approx 0.01$) which leads to a much larger photon flux on the sample. Another advantage is the possibility of selecting the excitation energy just below a matrix element with high concentration and just above the absorption edge of the element of interest (selective excitation), with the
A drawback, however, of an increased background caused by Raman scattering.

The combination of TXRF with SR can be achieved with various geometrical arrangements for reflector and detector. Figure 24 shows three possibilities. For geometry in Figure 24(a) the polarization effect is fully utilized by positioning the detector axis in the plane of the orbit. Scattered radiation is not emitted in this direction. The sample is excited efficiently and there is full homogeneous illumination of the sample by the width of the beam in the horizontal plane. There are hardly any losses due to the collimators because the beam is naturally collimated in the vertical plane 0.1–0.2 mrad depending on the energy. The detection of the fluorescence signal is not optimal because the detector must be positioned sideways in order to make use of the polarization effect. The fluorescent radiation follows a long path in the sample before reaching the detector.

The excitation conditions for the arrangement as displayed in Figure 24(b) are poor. Most of the photons in the horizontal plane are absorbed in the collimation system. The intensity distribution in the vertical plane drops drastically and therefore the fluorescence intensity also drops with the deviation of sample regions from the plane of reference. Thus restriction to a 2–4-mm sample diameter is advisable because of the intensity and polarization distribution in the vertical plane. However, the detection efficiency is perfect because of the large solid angle. Excellent excitation and detection will be achieved with the arrangement shown in Figure 24(c). This combination of sample–detector position results in a complete loss of the polarization effect. If the sample is small, which is the case in ultratrace analysis, the scattering contribution from the sample itself is negligible. Scattering from the substrate is reduced by total reflection.

If the experiments are performed in air, scattering of the exciting radiation contributes to the background. Therefore, all measurements have to be done in a vacuum chamber and give excellent results.

A group from Atominstitute, Vienna, have performed experiments at HASYLAB, DESY Hamburg, Beamline L, which is a beamline bending magnet. Details are described by Wobrauschek and Streli.²⁶ The arrangement can be seen in Figure 25 following geometry shown in Figure 24(b) with a vertical reflector and sideways detector. The beam is collimated by a primary slit system and then impinges on the ML monochromator, after the monochromator the primary beam is absorbed by a beamstopper. Shielding the vacuum chamber is extremely important because there are always multiple scattered high-energy photons which would penetrate into the measuring chamber through the Al wall. The beam is totally reflected on a rectangular Suprasil reflector which
has a Ta plate at the front edge to prevent scattering on the front edge. A typical multielement spectrum is shown in Figure 26, excited with 17.5 keV simulating a Mo tube. Figures 27 and 28 show the extension to higher \( Z \) elements, setting the monochromator at 31 keV and at 70 keV. Detection limits can be found in Table 3. Detailed information concerning the experiments is given by Wobrauschek et al.\(^{79–81}\)

also some other groups made SR/TXRF experiments, in Japan\(^{82–85}\) in USA (NSLS, National Synchrotron Light Source\(^{86}\) and SSRL, Stanford Synchrotron Radiation Laboratory\(^{87}\) and Italy (Frascati).\(^{88}\)

As pointed out in the section on Applications, the semiconductor industry requires very low detection limits in the femtogram range or \( 10^8 \) atoms cm\(^{-2}\) level for the analysis of wafer surface contaminations at ultratrace levels.

SR/TXRF is an interesting tool for this task. Experiments were performed at HASYLAB in cooperation with Wacker Siltronic, leading to detection limits of 13 fg or $1.3 \times 10^8$ atoms cm$^{-2}$ for Ni, assuming an inspected area of 1 cm$^2$. Figure 29 shows the relevant spectrum. The group at SSRL (Pianetta, Brennan, Fischer-Colbry, Ladderman) established an instrument for routine wafer analysis at SSRL Beamline 6-2. With its offer of a clean environment, automatic wafer handling (150 mm as well as 200-mm wafers), wafer mapping with detection limits of $3 \times 10^8$ atoms cm$^{-2}$ for transition metals meets the requirements of the wafer industry perfectly. A focused wiggler beamline with a double ML monochromator is used. The wafer is held by a combined vacuum–electrostatic chuck in the vertical position, the detector is sideways and measurements are performed under vacuum conditions. At ESRF (European Synchrotron Radiation Facility) there is a project performing under vacuum conditions. At ESRF (European Synchrotron Radiation Facility) there is a project being realized on an Undulator beamline.\(^{(89,90)}\) A Si(111) double monochromator will be used as well as a ML monochromator. The wafer will be held by a chuck in a horizontal position and two detector arrays consisting of seven elements in a sideways geometry will be established, measuring the fluorescence radiation. It is also planned to measure low-Z elements down to Na. Detection limits below $10^8$ atoms cm$^{-2}$ are proposed for 200 and 300-mm wafers.

### 13 TOTAL REFLECTION X-RAY FLUORESCENCE ANALYSIS OF LOW-Z ELEMENTS

There is a lack of analytical methods for performing nondestructive and rapid multielement analyses of light elements at trace levels. TXRF can meet these requirements,\(^{(96,97)}\) if a special spectrometer adapted to the specific problems of the ED detection of low-energy radiation is used. The detection limits achievable are mainly influenced by the type of excitation source, which should provide a large number of photons with an energy near the K-absorption edge of these elements (from 200 eV upwards). The determining factor is the integral over the source spectrum of the intensity multiplied by the photoelectric absorption coefficient ($I(E)\tau(E)dE$). Since the absorption coefficient $\tau(E)$ drops steadily as the energy $E$ increases above an element’s absorption edge, X-ray tubes with standard anode materials (e.g. Sc, Cr, Cu) are poor exciters for light elements as their characteristic emissions are far above the absorption edges. To improve the sensitivity for light elements it is necessary to use either an X-ray tube which emits intensive characteristic radiation as close as possible to the absorption edges of the interesting element, or SR with its continuous spectral range down to low energies.

The spectrometer used for the experiments described in the following section is characterized in detail by Streli et al.\(^{(98)}\) A special ED Ge(HP) detector is used that meets all the requirements for low-energy detection. It has a thin entrance window (diamond window, 0.4-µm thick, transmission for oxygen $K\alpha = 85\%$), an ion implanted contact layer, a thin deadlayer and low-electronic noise contributions (fwhm (5.9 keV) = 125 eV). Measurements are performed under vacuum conditions to reduce absorption. A Cr 1300 W tube is used under standard conditions and a W/C ML is used for monochromatization. Details are described by Streli et al.\(^{(99)}\)

To improve the excitation conditions a windowless X-ray tube was used. Various anode materials have been tested after the take-off angle of the X-ray tube had been optimized to obtain a high photon flux on the sample. Optimization was effected with respect to the brilliance required and the self-attenuation of the emitted photons in the anode. Al, Si and Mo were tested as anode materials. Si offers the advantage of a high $\tau$ value for Al, but a low one for Si, which is mainly used as reflector material. For the analysis of impurities on Si-wafer surfaces this is especially an advantage, because the intensity of Si is reduced and cannot saturate the detector. Figure 30 shows the beam path of the spectrometer. Details are described in Streli et al.\(^{(100)}\) Detection limits obtained differ greatly with the excitation conditions. The standard Cr tube provides about 90 pg for Mg, and with the windowless Si-anode tube 7 pg were obtained. Figures 31 and 32 show spectra.

Using SR as an excitation source offers the advantage of an intense naturally collimated X-ray beam with a wide spectral range, which is also in the low-energy region. Therefore, SR is the ideal source for exciting
light elements efficiently. Experiments were performed at SSRL, at Beamline III-4. This beamline is equipped with a horizontally deflecting toroidal Au-mirror to cut off photons with an energy higher than 3 keV. A differential pumping system offers the possibility of connecting the measuring chamber directly without any window. Different kinds of filters can be inserted. A double ML monochromator can be inserted in the beam and removed easily. Figure 33 shows the schematic arrangement. The TXRF vacuum chamber was connected to the monochromator chamber directly with a flexible coupling and an interlock valve which closes the main valve upstream if the pressure exceeds 10^{-3} mbar. Because of the downlooking detector, the advantage of linear polarization of SR could not be used. Details are described by Streli et al.\textsuperscript{(101,102)}. To adapt the spectral distribution for analysis on Si wafer surfaces a 12-μm Si filter was inserted, leading to “quasimonochromatic” radiation with a bandwidth of about 400 eV, below the absorption edge of Si.

An interesting and promising application of low Z-TXRF is the quality control of Si wafer surfaces. Al

**Figure 31** Spectrum measured with the low Z-TXRF spectrometer using a standard Cr fine focus tube.

**Figure 32** Spectrum measured with the low Z-TXRF spectrometer using a Si-anode windowless tube.

**Figure 34** Spectrum of a Mg sample on a Si wafer measured at SSRL, Beamline 3–4.
and Na are elements of interest for the semiconductor industry, influencing the production yield of ICs negatively. Therefore it is very important to have an analytical method sensitive enough for the analysis of ultratrace of these elements. Droplet samples of 100 pg of Mg were prepared on Si wafer surfaces and analyzed with the set-up described using SR. The best results are found with “quasimonochromatic” SR, 62 fg for Mg (see Figure 34). Details are described by Purba et al.\(^\text{49}\).

In analyzing low-Z elements with an ED detector, the problem of overlapping L and M-lines from higher Z elements is critical and has to be considered, as well as the fact that low-energy radiation is more easily absorbed and has to be controlled, if the thin film criterion is valid for the matrix under investigation.

14 CONCLUSIONS AND OUTLOOK

TXRF has become accepted worldwide and is the applied method for trace element analysis in various kinds of samples. Owing to the LLDs in the picogram range (for standard X-ray tube excitation) and the requirement for only small sample volume/mass and simultaneous multielement capability, the range of application is wide. At the moment the application for quality control for Si wafer surfaces at ultratrace levels is the most prevalent use, because of the nondestructive and spatial resolution of the method. The possibility of surface analysis due to the angle dependence of the fluorescence signal indicates promising applications like thin film analysis and nondestructive depth profiling. Using SR as an excitation source reduces the detection limits down to the femtogram level. The main application at present is in the field of semiconductor surface analysis.

Generally TXRF has become a relevant competitor with other analytical methods in the ultratrace range due to the manyfold interdisciplinary applications, where the analytical power of TXRF in the sense of detectable elemental range, detection limits, stability, accuracy and precision, almost background-free spectra and simple quantification can be usefully applied.

1 Introduction

The need for femtosecond time resolution in the analysis of processes governed by atomic motion is well established. In biology, chemistry, and physics different times are of interest, but the shortest relate to the vibration of matter, being typically about $10^{-13}$ s (100 femtoseconds).

Time-resolved experiments are used to monitor time-dependent processes. Depending on the spectral range of observation, different properties can be studied. Usually, visible or near-visible radiation provides information on the electronic properties, but atomic motion can be directly monitored only through very short wavelength radiation, such as X-rays. The electronic changes associated with vibrations in single molecules, liquids or crystal lattices, isomerization and the breaking or formation of chemical bonds, can be monitored by ultrafast optical spectroscopy techniques, but the accompanying ultrafast structural rearrangements cannot be directly observed. In the detailed characterization of structures at the atomic level, X-ray and electron diffraction is an unparalleled tool, allowing reaction intermediates to be followed.

Synchrotrons have become essential to the study of structures. Nevertheless, the shortest durations attainable with the latest generation of synchrotrons, hold the time resolution of experiments around 50 ps. This article shows how subpicosecond time resolution can be achieved in the analysis of very short-lived transient structures. The two emerging techniques in subpicosecond time-resolved X-ray (electron) diffraction are (1) ultrashort X-ray (electron) probe pulses, produced through a femtosecond laser system, and (2) fast X-ray detection during quasicontinuous synchrotron-produced X-ray probe illumination.

1 INTRODUCTION

Atoms share their outer-shell electrons to establish the bonds that build the structures of solids, molecules, and macromolecules. Strict energetic laws govern the movement of electrons, atoms, and molecules. At room temperature, atoms and molecules vibrate at a few hundred femtoseconds. When excited, these atoms may redistribute themselves inside their environment. Molecules may twist, to establish and destroy bonds. These basic ultrafast atomic displacements are at the origin of many processes, even though the expected event is reached sometimes a few seconds later, following transitions through multiple intermediate states. The ideal would be to follow a reaction – at the atomic level – en route from reactant to product. However, bond dissociation and atomic displacement following charge transfer or isomerization have been shown to occur in the femtosecond timescale. The subpicosecond transient structures involved are critical to the understanding of the first steps of elementary processes such as vision, oxygen transport in hemoglobin, or phase transitions such as the melting of a solid.

The scattering properties of fully ordered (crystalline) or poorly ordered (fluid) matter on electrons and X-rays can directly reveal its structure through atomic spatial resolution. KEV X-radiation ($\lambda \approx 1$ Å) scatters mainly with the core electrons. The interferences that occur between electromagnetic waves produced from all the scattering centers – periodically positioned within the crystal – lead to a diffraction pattern which is very sensitive to the atomic structure of the material. In comparison to X-rays, electrons interact directly with the nuclei of the atoms by elastic scattering. Being several orders of magnitude stronger than X-ray scattering, this process is efficiently used in gas-phase structure determination, instead of X-ray diffraction. Since the mid-1990s significant advances have occurred towards picosecond and subpicosecond time-resolution in diffraction experiments. Using 100 fs time-resolved X-ray diffraction, the picosecond transient behavior of atomic disordering in a Langmuir–Blodgett (LB) organometallic film has been resolved, following ultrashort laser
pulse excitation\(^{(7)}\). At UCSD (University of California, San Diego), picosecond time resolution with very high spatial resolution (\(\mu\text{m}\)) has been demonstrated in the ultrafast nonthermal melting of GaAs crystal\(^{(8,9)}\). The laser energy transport (disordering, optical phonon, acoustic phonon) in an InSb crystal was analyzed with a resolution of 300\(\text{fs}\) by X-ray diffraction\(^{(10)}\). In less than 20 years, the time resolution of X-ray diffraction experiments has increased by five orders of magnitude, owing to the maturation of laser-produced plasma X-ray sources (Figure 1). At present only the few most intense Bragg reflections of a crystal can be studied at such temporal resolutions, excluding the analysis of complex systems. The analysis of intermediate states in time-resolved protein crystallography requires thousands of Bragg reflections. Such high numbers of reflections can be obtained with synchrotrons using Laue geometry, but the time resolution is limited to the 50\(\text{ps}\) shortest X-ray burst achievable with the present third-generation devices\(^{(6)}\).

As with crystal X-ray diffraction, gas phase electron diffraction was soon recognized for the analysis of molecular structures in their ground state\(^{(6,11)}\). The first investigations of transient excited molecular species were with a pulsed 1\(\mu\text{s}\) electron beam (\(\approx10\text{keV}\)), electromagnetically chopped and synchronized with the exciting laser pulse. High temporal resolution resulted from the subsequent production of short laser-driven electron sources (Figure 2). Picosecond time-resolution has been demonstrated in the studied photochemical processes\(^{(12,13)}\). Electron diffraction is also extensively used to characterize solid surfaces. The escape depth of electrons at energies of a few hundreds of electron volts is limited to 10\(\text{Å}\), whereas electrons at higher energies (few tens of keV) may probe several atomic layers. Experiments have recently been performed at a few picoseconds resolution\(^{(6)}\).

2 ULTRAFAST TIME RESOLUTION

There are two methods with which to reach subpicosecond time resolution for the analysis of ultrafast atomic conformation changes. Both require an optical pump pulse to excite the sample for less time than the ultrafast process under study.

2.1 High-speed Detectors

One method is to use long X-ray or electron beams associated with a fast detector, such as a streak camera (Figure 3)\(^{(6,14,15)}\). The principle of the fast detector is displayed in Figure 4. At the photocathode, the radiation is converted into an electron beam which is accelerated to few tens of keV and streaked by pulsed electrostatic fields. The time resolution is mainly limited by the initial electron energy dispersion at the photocathode.
In the other method (Figure 3), both the optical pump and X-ray or electron pulses are short and come from the same laser system, thus preventing any temporal jitter. For a long time, short optical laser pulses have been the only way to probe ultrafast phenomena in biochemistry and physics. Using this method, the output energy has now become high enough to produce these intense electron or X-ray bursts directly for transient states analysis. The detector can be large and very efficient and single-shot experiments are achievable.

### 3 ULTRAFAST X-RAY DIFFRACTION

#### 3.1 Femtosecond X-ray Sources

Laser-produced plasmas from 100 fs intense laser systems are good candidates to produce subpicosecond X-ray sources.\(^{16–21}\) The energy deposited at the surface of a solid-state target produces a high temperature (500 eV) and a dense plasma which remains at near-solid densities during the interaction because it has no time to expand. In such plasmas, high ionization stages of ions are reached and strong nonequilibrium states are produced. X-ray emission produced from this thermal plasma lasts longer than the laser pulse duration because it takes few picoseconds to be quenched by cooling. However, at laser peak power densities around \(10^{17}\) W cm\(^{-2}\), strong nonlinear processes accelerate some plasma electrons to energies of 10–60 keV. As shown in Figure 5, these fast electrons penetrate inside the solid target deeper than the plasma depth and lose their energy mainly by K-shell ionization of the atoms producing monochromatic K\(_x\) X-radiation. At LOA (Laboratoire d’Optique Appliquée), the efficiency of X-ray sources\(^{20,21}\) has now reached 7–10\(^{15}\) photons per steradian can be produced at 7.12 Å. To date, these laser-produced plasma X-ray bursts are the most intense that can be produced in the 100 fs timescale. Third-generation synchrotrons cannot reduce

![Diagram of a streak camera principle](image)
X-ray source from laser-produced plasma experiments.

X-ray pulse durations below a few tens of picoseconds.\(^6\) At ESRF (European Synchrotron Radiation Facility), 50 ps X-ray flashes can contain \(10^7\) collimated photons at 8 keV and \(10^{11}\) collimated photons within the range 7–11 keV. Thomson scattering of 100 fs intense laser pulses of such electron bunches may significantly reduce the available pulse duration from such systems. At the ALS (Advanced Light Source) synchrotron in Berkeley, \(10^5\) collimated X-rays at 30 keV and with a pulse duration of 300 fs have been produced.\(^22\) At UCI (University of California, Irvine), a bunch of photoelectrons is produced on a photocathode by a 100 fs laser beam. These electrons are then accelerated to few 10 keV and focused onto the anode, producing \(10^4\) sr\(^{-1}\) monochromatic Ka photons.\(^6\) The X-ray pulse duration is limited to few picoseconds due to temporal broadening of the electron beam from the coulombic repulsion between electrons during their transport from the photocathode to the anode.

3.2 Operating Principles

The first experiments with subpicosecond time resolutions have recently been realized on simple systems using ultrafast X-ray sources.\(^7,9,10,23\) In these experiments, first-order X-ray Bragg reflections are used to analyze the lattice strain and the disordering of atoms inside the surface of simple crystals following its excitation by an optical 100 fs laser pulse. Being produced by the same laser system, the exciting pulse and the probe X-ray flash are perfectly synchronized. The X-ray flash duration gives the resolution at which the atomic dynamics is probed and the delay lines on both laser arms allow X-ray probing of the sample before, during, and after its excitation. A spectral shift of the Bragg reflection provides information on the transient atomic plane spacing being compressed or expanded. The width of the transient rocking curve is the signature of the lattice correlation length over which each atomic plane gives a similar contribution to the scattering amplitude. It is inversely proportional to the number of atomic planes \((n)\) participating coherently in the diffraction, i.e. \(W_B = (2\pi n/tg q_B)^{-1}\). Thus, high spectral resolution of the width of the transient rocking curves may allow propagation of the perturbation inside the lattice to be observed over the stationary correlation length. It may also give information on the homogeneity of the sample excitation by the pumping laser. Finally, the peak intensity is a signature of the remaining order/disorder of the diffracting atoms inside the correlation length.

3.3 Experiments

Table 2 summarizes experiments with the available ultra-fast X-ray sources. The LOA experiment demonstrates that laser-produced plasma X-ray sources can follow simple atomic processes lasting less than 1 ps with a time resolution of 100 fs. The spatial resolution was kept low enough (0.3 Å) to maintain high signal-to-noise ratio data acquisition. However, laser-produced plasma X-ray sources can provide high spatial resolution, as shown in the UCSD experiment in which mÅ precision was reached.

As an example of such experiments, the LOA setup is shown in Figure 6. The 7.12 Å Ka X-ray radiation emitted from a silicon target is collected over a solid angle of \(7.4 \times 10^{-3}\) sr by a toroidally bent quartz crystal (100) and focused onto the sample. The X-ray focal spot contained \(5.8 \times 10^4\) photons per shot for efficient laser–solid coupling. The first-order Bragg reflection

Figure 6 Experimental set-up for ultrafast X-ray diffraction experiments.

(3.6° Bragg angle), of a cadmium arachidate LB film was analyzed. The structure of the 3500 Å thick LB film is shown in Figure 6. This fatty acid salt has a polar head group, where the cadmium atom is located, and a long hydrophobic tail. When deposited on a glass substrate by the LB technique, the Cd arachidate molecules form a multilayer film, with alternating orientation of the layers: head group against head group and hydrophobic tail against hydrophobic tail. This places the cadmium atoms in well-defined planes with a separation of 55 Å. The 300 × 75 µm² X-ray focal spot was stretched onto the sample's surface to 1.2 mm. The Bragg reflection was detected by a cooled X-ray CCD camera, allowing the measurement of the low amplitude signals which do not exceed 40 diffracted photons in one laser shot.

The transient diffracted signal is studied as a function of the delay between the X-ray pulse and a pumping laser pulse used to perturb the sample at fluxes ranging from 1.8 J cm⁻² to 26.7 J cm⁻². One experimental run consisted of five reference shots without the pumping beam on a fresh surface, one shot with the pumping beam on and five shots without the pumping beam in order to probe the damaged area.

For all fluxes, a 75% decrease of the diffracted X-ray intensity was observed in a timescale from few hundreds of femtoseconds to few tens of picoseconds, depending on the energy of the exciting pulse. Results are shown in Figure 7 for four different pumping fluxes. The time response of the film is 15 ps at 1.8 J cm⁻². It drops down to 1 ps at 11.8 J cm⁻² and is lower than 600 fs at 27.6 J cm⁻². This loss in diffracted intensity can be understood as a disordering of the diffracting atoms produced inside each cadmium layer before any thermal expansion of the lattice has time to occur.

Using the Debye–Waller theory, a broadening of 8 Å of the electronic density in each layer of the film must be induced to provide the 75% loss of diffracted X-ray intensity. At higher than 27 J cm⁻², the signal-to-noise ratio on the detector becomes very poor due to X-ray emission produced from the sample itself, which hides the transient diffracted X-ray signal. Such large atomic displacements occurring in less than 1 ps probably come from the very specific film structure. In fact, each film layer contains two layers of cadmium atoms separated by 3 Å and the distance between two atoms is about 5 Å. At high pumping intensities (10¹⁴ W cm⁻²), bonds are broken and atoms are ionized; ions then experience strong electrostatic repulsions. Rough numerical simulations, not taking into account the influence of the organic chains, are consistent with the observed subpicosecond film time response. In the case of the LB film, cadmium atoms experience weak ionic bonding with the carboxyl group of the organic chain. Experiments were conducted on thallium acid phthalate crystals in which the thallium atoms are strongly linked to the crystal structure by four covalent bonds. At high pumping fluxes (21 J cm⁻²), the time response is found to be 3 ps, much slower than for the film at the same flux. This confirms the ability of the LB film to experience high disordering.
4 ULTRAFAST ELECTRON DIFFRACTION

4.1 Electron Femtosecond Sources

The production of femtosecond electron bunches takes advantage of developments in streak camera technology.\(^{12,13,26–28}\) Femtosecond electron bunches are produced from femtosecond laser pulses focused on negatively biased photocathodes. Ejected photoelectrons are accelerated to energies around a few tens of kilo electron volts and are focused onto the sample instead of being streaked in the case of streak camera operations. Figure 8 reports the experimental data obtained at CALTECH (California Institute of Technology) using this technology. A temporal broadening of 3 ps is already produced for 1000 electrons in the packet due to coulombic repulsion inside the beam.\(^{12}\) Subpicosecond time resolution may be reached with very few electrons in the packet and a highly efficient detector.

4.2 Operating Principles

In contrast to X-rays, electrons are scattered by the electronic density cloud and by the nuclei of the atoms. The intensity of scattering is then orders of magnitude larger than for X-rays. Electron scattering is well suited to probe less-dense matter, such as gas-phase samples, and is also used to probe solid-state surfaces up to few 100 Å thicknesses.\(^{29–31}\) As shown in Figure 9, information on the internuclear distances is projected as a macroscopic diffraction diagram made of concentric rings of radius equal to the amplitude of the momentum transfer vector \(s\). Fourier inversion of the signals gives a direct snapshot of the interatomic distance for each delay following the excitation. The calculations for the dissociation of IBr, also shown in this figure, demonstrate that time-dependent phenomena can be resolved with a shorter resolution than the width of the electron probe pulse.\(^{6}\)

4.3 Experiments

Two kinds of experiments have been carried out. The smallest time resolution to date is 4 ps, obtained at
CALTECH by using back-illuminated streak camera technology. The C–I and I–I internuclear distances were followed in the photodissociation of CH₂I₂. Two other groups, at Arkansas and Norfolk, have demonstrated time a resolution of few tens of picoseconds from a front-illuminated streak camera.

5 CONCLUSIONS

The important challenge in electron time-resolved diffraction is now to demonstrate subpicosecond resolution in gas-phase experiments. For ultrafast time-resolved X-ray diffraction experiments, the available X-ray photon flux prevents any subpicosecond or picosecond time-resolved experiments on low-Z materials, even in the solid phase. Furthermore, the study of more complex structures requires the analysis of thousands of Bragg reflections and the potential use of laser-produced plasma X-ray sources strongly depends on an ability to demonstrate new X-ray diffraction geometries. Synchrotrons provide polychromatic and collimated X-ray beams. A static Laue diffraction pattern of Photo Yellow Protein, with an X-ray flash lasting 50 ps, has been obtained. Dynamic studies might follow this result. However, the available third-generation technology will not permit shorter time resolutions. The laser-produced plasma X-ray source is highly monochromatic and divergent. According to the Bragg law, this is another way to pick up many Bragg reflections inside the sample, as shown in Figure 10.

For a triclinic crystal of lysozyme illuminated with 20 × 100 mrad² 1.54 Å X-rays, we have estimated a 42-min accumulation time at 10 Hz to be necessary to reach a minimum of 10²–10³ photons in each spot with the available X-ray flux (2 × 10⁹ photons/µrad²/shot). This new geometry will really open up new capabilities in ultrafast time-resolved X-ray diffraction experiments.

When an element is bombarded by high-energy particles, orbital electrons may be ejected creating inner orbital atomic vacancies. These vacancies may be filled by transition of outer level electrons giving rise to characteristic X-radiation. X-ray fluorescence spectrometry provides the means of the identification of an element by measurement of its characteristic X-ray emission wavelength of energy. The method allows the quantization of a given element by first measuring the emitted characteristic line intensity and then relating this intensity of element concentration. While the roots of the method go back to the early part of this century, where electron excitation systems were employed, it is only during the last 30 years or so that the technique has gained major significance as a routine means of elemental analysis. Wavelength-dispersive spectrometers employ diffraction by a single crystal to separate characteristic wavelengths emitted by the sample. Today, nearly all commercially available X-ray spectrometers use the fluorescence excitation method and employ a sealed X-ray tube as the primary excitation source. The first commercial X-ray spectrometer became available in the early 1950s and although these earlier spectrometers operated only with an air path, they were able to provide qualitative and quantitative information on all elements above atomic number 22 (titanium). Later versions allowed use of helium or vacuum paths that extended the lower atomic number cut-off to around atomic number 9 (fluorine). X-ray detectors used include the flow counter, the scintillation counter and the Si(Li) detector.

The X-ray method has good overall performance characteristics. In particular, the speed, accuracy and versatility of X-ray fluorescence are the most important features among the many that have made it the method of choice in over 30 000 laboratories all over the world. Most wavelength-dispersive spectrometers fall into two broad categories – single channel and multichannel. Single channel spectrometers are typically employed for both routine and nonroutine analysis of a wide range of products, including ferrous and nonferrous alloys, oils, slags and sinters, ores and minerals, thin films, and so on. These systems are very flexible but relative to multichannel spectrometers are somewhat slow. The multichannel wavelength-dispersive instruments are used almost exclusively for routine, high-throughput analysis where the great need is for fast accurate analysis, but where flexibility is of no importance.

Interelement (matrix) effects often complicate quantitative analysis by X-ray fluorescence. However, a wide selection of methods is now available for minimizing these
effects, allowing excellent accuracy to be obtained in many cases. Detection limits are achievable down to the low parts per million (ppm) range and it is possible to obtain reasonable responses from as little as a few milligrams of material.

1 INTRODUCTION

Much of the basic physics of X-ray production, absorption, scatter and diffraction has been covered in X-ray Techniques: Overview. The following section briefly reviews this material.

1.1 Properties of X-radiation

In the analysis of a specimen, both the incoming primary X-ray beam and the secondary fluoresced beam will be attenuated by an amount which can be theoretically described or modeled from practical experiments. The effect of absorption is typically to produce nonlinearity in a calibration curve of elemental concentration versus X-ray response. Scattering occurs when an X-ray photon interacts with the electrons of the target element. Where this interaction is elastic, that is no energy is lost in the collision process, the scattering is referred to as coherent (Rayleigh) scattering. Since no energy change is involved, the coherently scattered radiation will retain exactly the same wavelength as that of the incident beam. It can also happen that the scattered photon gives up a small part of its energy during the collision, especially where the electron with which the photon collides is only loosely bound. In this instance, the scatter is referred to as incoherent (Compton scattering). X-ray diffraction is a combination of two phenomena – coherent scatter and interference. At any point where two or more waves cross one another, they are said to interfere. The principal of superposition is that the resulting displacement, at any point and at any instant, may be formed by adding the instantaneous displacements that would be produced at the same point by independent wave trains, if each were present alone. Under certain geometric conditions, wavelengths that are exactly in phase may add to one another, and those that are exactly out of phase may cancel each other out. Under such conditions coherently scattered photons may constructively interfere with each other giving diffraction maxima (Equation 1):

\[ n\lambda = 2d\sin\theta \]  

(1)

where \( n \) is an integer. Equation (1) is a statement of Bragg’s law. Bragg’s law is important in wavelength-dispersive spectrometry since by using a crystal of fixed \( 2d \), each unique wavelength \( \lambda \) will be diffracted at a unique diffraction angle (Bragg angle). Thus, by measuring the diffraction angle \( \theta \), knowledge of the \( d \)-spacing of the analyzing crystal allows the determination of the wavelength. Since there is a simple relationship between wavelength and atomic number, as given by Moseley’s law, one can establish the atomic number(s) of the element(s) from which the wavelengths were emitted.

1.2 General Applications of X-rays

X-ray photons are produced following the ejection of an inner orbital electron from an excited atom, and subsequent transition of atomic orbital electrons from states of high to low energy. Each element present in the specimen will produce a series of characteristic lines making up a polychromatic beam of characteristic and scattered radiation coming from the specimen. This polychromatic beam is then directed to the spectrometer where individual wavelengths (or energies) can be measured. X-ray spectrometric techniques provided important information for the theoretical physicist in the first half of this century and since the early 1950s they have found an increasing use in the field of materials characterization. While most of the early work in X-ray spectrometry was carried out using electron excitation, today, use of electron-excited X-radiation is restricted mainly to X-ray spectrometric attachments to electron microscopes. Most modern stand-alone X-ray spectrometers use X-ray excitation sources rather than electron excitation. X-ray fluorescence spectrometry typically uses a polychromatic beam of short wavelength X-radiation to excite longer wavelength characteristic lines from the sample to be analyzed. Modern X-ray spectrometers use either the diffraction power of a single crystal to isolate narrow wavelength bands, or a proportional detector to isolate narrow energy bands, from the polychromatic radiation (including characteristic radiation) excited in the sample. The first of these methods is called wavelength-dispersive spectrometry and the second, energy-dispersive spectrometry (see Portable Systems for Energy-dispersive X-ray Fluorescence). Because the relationship between emission wavelength and atomic number is known, isolation of individual characteristic lines allows the unique identification of an element to be made and elemental concentrations can be estimated from characteristic line intensities. Thus this technique is a means of materials characterization in terms of chemical composition.

1.3 Historical Development of X-ray Spectrometry

X-ray fluorescence spectrometry provides the means of identification of an element by measurement of its characteristic X-ray emission wavelength or energy. The method allows the quantization of a given element by first
measuring the emitted characteristic line intensity and then relating this intensity to elemental concentration. While the roots of the method go back to the early part of this century, it is only during the last 30 years or so that the technique has gained major significance as a routine means of elemental analysis.\(^{(2)}\) The first use of the X-ray spectrometric method dates back to the classic work of Henry Moseley.\(^{(3)}\) In Moseley’s original X-ray spectrometer, the source of primary radiation was a cold cathode tube in which the source of electrons was residual air in the tube itself, the specimen for analysis forming the target of the tube. Radiation produced from the specimen then passed through a thin gold window onto an analyzing crystal whence it was diffracted to the detector. One of the major problems in the use of electrons for the excitation of characteristic X-radiation is that the process of conversion of electron energy into X-rays is relatively inefficient: about 99% of the electron energy is converted to heat energy. This means in turn that it may be difficult to analyze specimens which are volatile or tend to melt. Nevertheless, the technique seemed to hold some promise as an analytical tool and one of the first published papers on the use of X-ray spectroscopy for real chemical analysis appeared as long ago as 1922, when Hadding\(^{(4)}\) described the use of the technique for the analysis of minerals.

Some time in the mid-1920s, it was suggested that one could use primary X-ray photons for the excitation of secondary characteristic X-ray spectra. The use of X-rays, rather than electrons, to excite characteristic X-radiation avoids the problem of heating the specimen. It is possible to produce the primary X-ray photons inside a sealed X-ray tube under high vacuum and efficient cooling conditions, which means that the specimen itself need not be subject to heat dissipation problems or the high vacuum requirements of the electron beam system. Use of X-rays rather than electrons represented the beginnings of the technique of X-ray fluorescence as we know it today. The fluorescence method was first employed on a practical basis in 1928 by Glocker and Schreiber.\(^{(5)}\) Unfortunately, data obtained at that time were rather poor because X-ray excitation is even less efficient than electron excitation. Also the detectors and crystals available at that time were rather primitive and thus the fluorescence technique did not seem to hold too much promise. In any event, widespread use of the technique had to wait until the mid-1940s when X-ray fluorescence was rediscovered (see Birks\(^{(2)}\)). The basis of their spectrometer was a diffractometer that had been originally designed for the orientation of quartz oscillator plates. A Geiger counter was used as a means of measuring the intensities of the diffracted characteristic lines and quite reasonable sensitivity was obtained for a very large part of the atomic number range.

The first commercial X-ray spectrometer became available in the early 1950s and although these earlier spectrometers operated only with an air path, they were able to provide qualitative and quantitative information on all elements above atomic number 22 (titanium). Later versions allowed use of helium or vacuum paths that extended the lower atomic number cut-off. Most modern commercially available X-ray spectrometers have a range from about 0.4 to 20 Å (40 to 0.6 keV) and this range will allow measurement of the K series from fluorine \((Z = 9)\) to lutetium \((Z = 71)\), and the L series from manganese \((Z = 25)\) to uranium \((Z = 92)\). Other line series arise from the M and N levels but these have little use in analytical X-ray spectrometry. In practice, the number of vacancies in electron levels resulting in the production of characteristic X-ray photons is less than the total number of vacancies created in the excitation process, because the atom can also regain its initial state by reorganization of atomic electrons without the emission of X-ray photons (the Auger process). This is an important factor in determining the absolute number of counts that an element will give under a certain set of experimental conditions. It is mainly for this reason that the sensitivity of the X-ray spectrometric technique is rather poor for the very low atomic number elements, since fluorescent yields for these low atomic numbers are very small.

Today, nearly all commercially available X-ray spectrometers use the fluorescence excitation method and employ a sealed X-ray tube as the primary excitation source. Some of the simpler systems may use a radioisotope source, because of considerations of cost and/or portability. While electron excitation is generally not used in stand-alone X-ray spectrometers, it is the basis of X-ray spectrometry carried out on electron column instruments. The ability to focus the primary electron beam allows analysis of extremely small areas down to a micrometer or so in diameter, or even less in specialized instruments. This, in combination with imaging and electron diffraction, offers an extremely powerful method for the examination of small specimens, inclusions, grain boundary phenomena, etc. The instruments used for this type of work may be in the form of a specially designed electron microprobe analyzer, or simply an energy or wavelength-dispersive attachment to a scanning electron microscope.

Over the past 30 years or so, the X-ray fluorescence method has become one of the most valuable methods for the qualitative and quantitative analysis of materials. Many methods of instrumental elemental analysis are available today and among the factors that will generally be taken into consideration in the selection of one of these methods are accuracy, range of application, speed, cost, sensitivity and reliability. While it is certainly true that no one technique can ever be expected to offer all of
the features that a given analyst might desire, the X-ray method has good overall performance characteristics. In particular, the speed, accuracy and versatility of X-ray fluorescence are the most important features among the many that have made it the method of choice in over 20,000 laboratories all over the world. Both the simultaneous wavelength-dispersive spectrometer and the energy-dispersive spectrometers lend themselves admirably to the qualitative and quantitative analysis of solid materials and solutions.

2 CHARACTERISTIC X-RAY WAVELENGTHS

X-ray Techniques: Overview showed that there are two basic types of X-radiation – white radiation (produced as the impinging high energy electrons are decelerated by the atomic electrons of the elements making up the specimen) and characteristic radiation. The relationship between the wavelength of a characteristic X-ray photon and the atomic number \( Z \) of the excited element was first established by Moseley. Moseley’s law is written as shown in Equation (2)

\[
\frac{1}{\lambda} = K(Z - \sigma)^2
\]

where \( Z \) is atomic number and \( K \) and \( \sigma \) are constants. Since there are two competing effects by which an atom may return to its initial state, and since only one of these processes will give rise to the production of a characteristic X-ray photon, the intensity of an emitted characteristic X-ray beam will be dependent upon the relative effectiveness of the two processes within a given atom. As an example, the number of quanta of K series radiations emitted per ionized atom is a fixed ratio for a given atomic number, this ratio being called the fluorescent yield.

An excited atom can revert to its original ground state by transferring an electron from an outer atomic level to fill the vacancy in the inner shell. An X-ray photon is emitted from the atom as part of this de-excitation step, the emitted photon having an energy equal to the energy difference between the initial and final states of the transferred electron. Each unique atom has a number of available electrons which can take part in the transfer and, since millions of atoms are typically involved in the excitation of a given specimen, all possible de-excitation routes are taken. These de-excitation routes can be defined by a simple set of selection rules that account for the majority of the observed wavelengths. Each electron in an atom can be defined by four quantum numbers. The first of these quantum numbers is the principal quantum number \( n \), which can take all integral values. When \( n \) is equal to 1, the level is referred to as the K level; when \( n \) is 2, the L level, and so on. \( \ell \) is the angular quantum number and this can take all values from \((n - 1)\) to zero. \( m \) is the magnetic quantum number and can take values of \(+\ell\), zero and \(-\ell\). \( s \) is the spin quantum number with a value of \( \pm \frac{1}{2} \). The total momentum \( J \) of an electron is given by the vector sum of \((\ell + s)\). Since no two electrons within a given atom can have the same set of quantum numbers, a series of levels or shells can be constructed. Table 1 gives the atomic structures of the first three principal shells.

As was shown in a previous chapter (see X-ray Techniques: Overview), the selection rules for the production of normal (diagram) lines require that the principal quantum number must change by at least one, the angular quantum number must change by zero or one. Transition groups may now be constructed, based on the appropriate number of transition levels. Application of
the selection rules indicates that in, for example, the K series, only LII → K and LIII → K transitions are allowed for a change in the principal quantum number of one. There are equivalent pairs of transitions for $n = 2$, $n = 3$, $n = 4$, etc. Figure 1 shows the lines that are observed in the K series. Three groups of lines are indicated. The normal lines are shown on the left-hand side of the figure and these consist of three pairs of lines from the LII/LIII, MII/MIII and NII/NIII sub-shells respectively. While most of the observed fluorescent lines are normal, certain lines may also occur in X-ray spectra that do not at first sight fit the basic selection rules. These lines are called forbidden lines and are shown in the center portion of the figure. Forbidden lines typically arise from outer orbital levels where there is no sharp energy distinction between orbitals. As an example, in the transition elements, where the 3d level is only partially filled, lines are called forbidden lines and are shown in the center portion of the figure. Forbidden lines typically arise from outer orbital levels where there is no sharp energy distinction between orbitals. As an example, in the transition elements, where the 3d level is only partially filled and is energetically similar to the 3p levels, a weak forbidden transition (the $\beta_5$) is observed. A third type of line may also occur: satellite lines, which arise from dual ionizations. Following the ejection of the initial electron in the photoelectric process, a short, but finite, period of time elapses before the vacancy is filled. This time period is called the lifetime of the excited state. For the lower atomic number elements, this lifetime increases to such an extent that there is a significant probability that a second electron can be ejected from the atom before the first vacancy is filled. The loss of the second electron modifies the energies of the electrons in the surrounding sub-shells, and other pairs of X-ray emission lines are produced, corresponding to the $K\alpha_5/K\alpha_6$. In the K series the most common of these satellite lines are the $K\alpha_5/K\alpha_4$ and the $K\alpha_5/K\alpha_6$ doublets. These lines are shown at the right-hand side of the figure. Although, because they are relatively weak, neither forbidden transitions nor satellite lines have great analytical significance, they may cause some confusion in qualitative interpretation of spectra and may even be misinterpreted as coming from trace elements.

3 ANALYZING CRYSTALS AND DISPERSION DEVICES

The angular dispersion $d\theta/d\lambda$ of a crystal of spacing $2d$ is given by Equation (3)

$$
\frac{d\theta}{d\lambda} = \frac{n}{2d \cos \theta}
$$

(3)

It will be seen from Equation (3) that the angular dispersion will be high when the $2d$-spacing is small. This is unfortunate as far as the range of the spectrometer is concerned, because a small value of $2d$ means in turn a small range of wavelengths coverable. Thus, as with the resolution and peak intensities, high dispersion can only be obtained at the expense of cutting the wavelength range covered by a particular crystal. In order to circumvent this problem, it is likely that several analyzing crystals will be employed in the coverage of a number of analyte elements. Many different analyzing crystals are available, each having its own special characteristics, but three or four crystals will generally suffice for most applications. Table 2 lists the more commonly used crystals. While the maximum wavelength covered by traditional spectrometer designs is about 20 Å, recent developments now allow the extension of the wavelength range significantly beyond this value.

Classically, large single crystals have been used as diffracting structures in the wavelength-dispersive spectrometer. The three-dimensional lattice of atoms is oriented and fabricated such that Bragg planes form the interatomic 2$d$-spacing for the wavelength in question. The selection of crystals for the longer (>8 Å) wavelength region is difficult, however, mainly because there are not

too many crystals available for work in this region. The most commonly employed crystal is probably thallium acid phthalate (TAP; 2d = 26.3 Å), and this allows measurement of the K lines of elements including magnesium, sodium, fluorine and oxygen. Several alternatives to single crystals as diffracting structures have been sought over the years including the use of complex organic materials with large 2d-spacings, gratings, and specular reflectors, metal disulfides, organic intercalation complexes such as graphite, molybdenum disulfide, mica and clays. For a comprehensive list of analyzing crystals see Bertin.\(^6\)

In addition to crystals and multilayer films, a third alternative became available in the late 1970s, this alternative being the layered synthetic microstructure (LSM). LSMS are constructed by applying successive layers of atoms or molecules on a suitably smooth substrate. In this manner, both the 2d-spacing and composition of each layer are selected for optimum diffraction characteristics, thus, to a certain extent, they can be designed and fabricated to give optimum performance for special applications. Typical experimental data show factors of about four to six times improvement in peak intensities compared to TAP, for the range of elements measured.

### 4 DETECTORS FOR X-RAY FLUORESCENCE

#### 4.1 Desirable Properties of an X-ray Detector

As was stated in X-ray Techniques: Overview, an X-ray detector is simply a transducer for converting X-ray photon energy into voltage pulses. In order to adequately define the properties of X-ray detectors it is necessary to define certain terms, which, while in common use, are often misused. Intensity (I) is a flux of radiation, measured in number of photons per steradian. It is, in effect, a measure of what comes out of the X-ray tube. The photons are converted to pulses by the detector generating a count rate (R), measured in pulses (counts) per second. The detector pulses are integrated for time \(t\) giving a number of counts (N). The ideal detector should possess certain important properties. These properties are quantum counting efficiency, linearity, proportionality and resolution, and are illustrated in Table 3. The table shows that a photon flux \(I_o\) is incident upon the detector, and a fraction \(I\) of this incident flux passes through the detector without producing ions within the detector. The quantum counting efficiency \(Q\) is expressed as \(I/I_o\). The property of linearity is also illustrated. Here, a number of X-ray photons are entering the detector at a rate of \(I\) photons per second, producing a rate of \(R\) pulses per second. Where \(R\) is proportional to \(I\) the detector is said to be linear. Linearity is important where the various count rates produced by the detector are to be used as measures of the photon intensity for each measured line. Table 3 also shows that when an X-ray photon of energy \(E\) enters the detector a pulse of \(V\) volts is produced. Where \(V\) is proportional to \(E\) the detector is said to be proportional. Proportionality is needed where the technique of pulse height selection is to be used. The last important detector property is associated with the use of pulse height selection and this property is the detector resolution. While each incident photon of energy \(E\) gives an average value of \(V\), there is a distribution in the value of \(V\) equal to \(\delta V\). This distribution is a measure of the detector resolution. Pulse height selection is a means of electronically rejecting pulses of voltage levels other than those corresponding to the characteristic line being measured. This technique is a very powerful tool in reducing background levels and the influence of overlapping lines from elements other than the analyte. The properties of proportionality and linearity are, to a certain extent, controllable by the electronics associated with the actual detector. To this extent, while it is common practice to refer to the characteristics of detectors, the properties of the associated pulse processing chain should always be included.

#### 4.2 Types of X-ray Detector

##### 4.2.1 The Gas Flow Proportional Detector

A gas flow proportional counter consists of a cylindrical tube about 2 cm in diameter, carrying a thin (25–50 μm) wire along its radial axis. The tube is filled with a mixture of inert gas and quench gas – typically 90% argon/10% methane (P-10). The cylindrical tube is grounded and around 1400–1800 V is applied to the central wire. The wire is connected to a resistor shunted by a capacitor. An X-ray photon entering the detector produces a number \(n\) of ion pairs, each comprising one electron and one argon positive ion. The first ionization potential for argon is about 16 eV, but competing processes during the conversion of photon energy to ionization cause the average energy required to produce an ion pair to be greater than this amount. The fraction relating the average energy to produce one ion pair, to the first

\[
\text{Table 3 Desirable properties of an X-ray detector}
\begin{array}{|c|c|c|}
\hline
\text{Property} & \text{Input} & \text{Output} & \text{Notes} \\
\hline
\text{Quantum efficiency} (Q) & \text{Photon flux } I_o & I \text{ transmitted} & Q = \frac{I}{I_o} \\
\text{Linearity} & \text{Intensity } I & \text{Count rate } R & R \propto I \\
\text{Proportionality} & \text{Photon energy } E & \text{Voltage } V & V \propto I \\
\text{Resolution} & \text{Photon energy } E & E \pm \delta V & R \propto \delta V \\
\hline
\end{array}
\]
ionization potential, is called the Fano factor $F$. For argon, $F$ is between $\frac{1}{2}$ and $\frac{1}{3}$ and the average energy $e_i$ required to produce one primary ion pair is equal to 26.4 eV. Equation (4) shows that the number of ion pairs produced by a photon of energy $E$ will equal:

$$n = \frac{E}{e_i}$$

(4)

Following ionization, the charges separate with the electrons moving towards the (anode) wire and the argon ions to the grounded cylinder. As the electrons approach the high field region close to the anode wire they are accelerated sufficiently to produce further ionization of argon atoms. Thus a much larger number $N$ of electrons will actually reach the anode wire. This effect is called gas gain, or gas multiplication, and its magnitude is given by $M$, where $M$ is equal to $N/n$. For gas flow proportional counters used in X-ray spectrometry $M$ typically has a value of around $10^5$. Provided that the gas gain is constant the size of the voltage pulse $V$ produced is directly proportional to the energy $E$ of the incident X-ray photon. In practice not all photons arising from photon energy $E$ will be exactly equal to $V$. There is a random process associated with the production of the voltage pulses and the resolution of a counter is related to the variance in the average number of ion pairs produced per incident X-ray photon. The resolution is generally expressed in terms of the full width at half-maximum of the pulse amplitude distribution. The theoretical resolution $R_t$ of a flow counter can be described by Equation (5):

$$R_t \% = \frac{128}{\sqrt{E}}$$

(6)

4.2.2 The Scintillation Detector

While the gas flow proportional counter is ideal for the measurement of longer wavelengths it is rather insensitive to wavelengths shorter than about 1.5 Å. For this shorter wavelength region it is common to use the scintillation counter. The scintillation counter consists of two parts, the phosphor (scintillator) and the photomultiplier. The phosphor is typically a large single crystal of sodium iodide that has been doped with thallium. When X-ray photons fall onto the phosphor, blue light photons are produced, where the number of blue light photons is related to the energy of the incident X-ray photon. These blue light photons produce electrons by interaction with a photosurface in the photomultiplier, and the number of electrons is linearly increased by a series of secondary surfaces, called dynodes, in the photomultiplier. The current produced by the photomultiplier is then converted to a voltage pulse, as in the case of the gas flow proportional counter. Since the number of electrons is proportional to the energy of the incident X-ray photon, the scintillation counter is a proportional counter.

Because of inefficiencies in the X-ray/blue-light/electron conversion processes, the average energy to produce a single event with the scintillation counter is more than a magnitude greater than the equivalent process in the flow counter. For this reason, the resolution of the scintillation counter is much worse than that of the flow counter. The theoretical resolution $R_t$ of the scintillation counter for photons of energy $E$ is given by Equation (6):

$$R_t \% = \frac{128}{\sqrt{E}}$$

(6)

4.2.3 The Si(Li) Detector (see Portable Systems for Energy-dispersive X-ray Fluorescence)

The Si(Li) detector consists of a small cylinder (about 1 cm diameter and 3 mm thick) of p-type silicon that has been compensated by lithium to increase its electrical resistivity. A Schottky barrier contact on the front of the silicon disk produces a p-i-n type diode. In order to inhibit the mobility of the lithium ions and to reduce electronic noise, the diode and its preamplifier are cooled to the temperature of liquid nitrogen. By applying a reverse bias of around 1000 V, most of the remaining charge carriers in the silicon are removed. Incident X-ray photons interact to produce a number $n$ of electron–hole pairs, as given in Equation (4), where, in this instance, $e_i$ is equal to about 3.8 eV for cooled silicon. This charge is swept from the diode by the bias voltage to a charge-sensitive preamplifier. A charge loop integrates the charge on a capacitor $C$ to produce an output pulse as in the case of the flow proportional counter, although in this case the $M$ term is equal to unity since the Si(Li) detector does not have an equivalent property to gas gain.

4.2.4 Other Detector Systems

Even though the Si(Li) detector is the most common detector used in energy-dispersive X-ray spectrometry, it is certainly not the only one. The higher absorbing power of germanium makes it an alternative for the measurement of high-energy spectra, and both cadmium telluride, CdTe, and mercuric iodide, HgI$_2$, show some promise as detectors capable of operating satisfactorily at room temperature. There are, however, many practical problems in the manufacture of these devices. As an example, in the preparation of CdTe, a Br–methanol etchant is used and the side product CdBr$_2$ has been found to poison the surface causing high leakage current with increase in background noise, but newer technology is reducing the problem and much lower backgrounds are now being reported. The major problem with HgI$_2$ is the growth of crystals of suitable size. The resolution
of the detector is, however, promising, making the rather tedious research worthwhile.

5 X-RAY SPECTROMETERS

5.1 X-ray Excitation Sources

As was discussed in X-ray Techniques: Overview, several different types of source have been employed for the excitation of characteristic X-radiation, including those based on electrons, X-rays, γ-rays, protons and synchrotron radiation. Most conventional wavelength-dispersive X-ray spectrometers use a high power (2 to 4 kW) X-ray bremsstrahlung source. In all cases, the primary source unit consists of a very stable high voltage generator, capable of providing a potential of typically 40 to 100 kV. The current from the generator is fed to the filament of the X-ray tube, which is typically a coil of tungsten wire. The applied current causes the filament to glow, emitting electrons in all directions. A portion of this electron cloud is accelerated to the anode of the X-ray tube, which is typically a water-cooled block of copper with the required anode material plated or cemented to its surface. The impinging electrons produce X-radiation, a significant portion of which passes through a thin beryllium window to the specimen. In order to excite a given characteristic line the source must be run at a voltage $V_o$ well in excess of the critical excitation potential $V_c$ of the element in question. The relationship between the measured intensity of the characteristic line $I$, the tube current $i$, and the operating and critical excitation potentials is shown in Equation (7):

$$ I = K_i (V_o - V_c)^{1.6} \quad (7) $$

The product of $i$ and $V_o$ represents the maximum output of the source in kilowatts. The optimum value for $V_o/V_c$ is 3 to 5. This optimum value occurs because at very high operating potentials the electrons striking the target in the X-ray tube penetrate so deeply into the target that self absorption of target radiation becomes significant. Since it is the intention to eventually equate the value of $I$ for a given wavelength or energy to the concentration of the corresponding analyte element, it is vital that, over the short term (1–2 h), both the tube current and voltage be stabilized to better than 0.1%. The current from the generator is fed to the tungsten filament of the X-ray tube. A sealed X-ray tube has an anode of Cr, Rh, W, Ag, Au or Mo and delivers an intense source of continuous and characteristic radiation, which then impinges onto the analyzed specimen, where characteristic radiation is generated. In general, most of the long wavelength excitation comes from the longer wavelength characteristic lines from the tube, and most of the short wavelength excitation from the continuous radiation from the tube.

Since the accuracy of any X-ray measurement will depend on the stability of the source it is important to understand exactly where any instability comes from. Table 4 shows that source drift is divided into four separate time-related zones: short, long, ultra-short and ultra-long. Most high voltage generators are designed to give a very low (0.05%) short-term drift. The effect of long-term drift can be calibrated out by use of internal standards. Ultra-long-term drift is mainly to do with X-ray tube aging and should be monitored on a monthly basis. The biggest problem is often the ultra-short-term drift. The stabilization circuits of the high voltage generator typically have a response time of a few hundred milliseconds. Thus if a short duration pulse (a transient) should enter the input of the generator, this may pass through giving a voltage spike with a resulting X-ray intensity spike. The solution here is to ensure that the quality of the mains supply is adequate.

5.2 X-ray Spectrometer Configurations

There are many different types of X-ray fluorescence instruments available, based on several different source and dispersion configurations. The most commonly employed instruments are based either on the wavelength-dispersive method or the energy-dispersive method (see Portable Systems for Energy-dispersive X-ray Fluorescence). Further subdivisions in the energy-dispersive instruments include primary or secondary source excitation mode; and in the case of wavelength-dispersive instruments, single channel (sequential) or multichannel (simultaneous). In all cases this may or may not include microprocessor control, and may or may not include a data processing computer. While each of these configurations has clear advantages over its competitors, each also has disadvantages – other than the obvious ones of cost and flexibility. Most instrument manufacturers continually strive to develop instruments that offer a good price/performance ratio, and that minimize some of the inherent limitations of a given procedure.

The function of the spectrometer is to separate the polychromatic beam of radiation coming from the specimen so that the intensities of each individual

characteristic line can be measured. A spectrometer should provide sufficient resolution of lines to allow such data to be collected, at the same time providing a sufficiently large response above background to make the measurements statistically significant, especially at low analyte concentration levels. It is also necessary that the spectrometer allow measurements over the wavelength range to be covered. Thus, in the selection of a set of spectrometer operating variables, four factors are important: resolution, response, background level and range. Due to many factors, optimum selection of some of these characteristics may be mutually exclusive as, for example, attempts to improve resolution invariably cause lowering of absolute peak intensities.

The wavelength-dispersive spectrometer may be a single-channel instrument in which a single crystal and a single detector are used for the sequential measurement of a series of wavelengths, or a multichannel spectrometer in which many crystal/detector sets are used to measure many elements simultaneously. In the typical wavelength-dispersive spectrometer geometry, a single crystal of known interplanar spacing is used to disperse the collimated polychromatic beam of characteristic wavelengths coming from the sample, such that each wavelength will diffract at a discrete angle. As was shown in X-ray Techniques: Overview, there is a simple relationship between the interplanar spacing of the crystal, the diffracted wavelength and the diffraction angle. Since the maximum achievable angle on a typical wavelength-dispersive spectrometer is around 73°, the maximum wavelength that can be diffracted by a crystal of spacing 2d is equal to about 1.9d.

5.3 Resolution of the Spectrometer

Many factors are significant in the design of an X-ray spectrometer, and not the least of these is the ability to disperse and separate the polychromatic beam of radiation coming from the excited specimen. In terms of the separating power of a crystal spectrometer this will be dependent upon two factors – the divergence allowed by the collimators (that to a first approximation determines the width of the diffracted lines) and the rocking angle of the crystal. Figure 2 shows a diagrammatic representation of the optical path of the spectrometer and shows radiation paths coming from the specimen, passing through a primary collimator, onto the surface of a crystal which diffracts over a range of ±θ. The radiation then passes through a secondary collimator to the detector. The reason why the crystal diffracts over a range of angles, as opposed to one discrete Bragg angle, is due to the mosaic nature of the crystal. In order to avoid problems such as secondary extinction, the surface of the single crystal analyzer is abraded. This process results in some broadening of the half-height width $B_{cr}$ of the diffracted beam. The divergence of the collimator $B_{cc}$ is determined by the length of the collimator blades and the spacing between the blades. The experimental breadth ($B_e$) of a diffracted line in a crystal spectrometer can be
Typical values for $B_e$ as far as the range of the spectrometer is concerned be high when the be seen from Equation (3) that the angular dispersion will influence of the breadth of the diffracted line profile. It will dispersion of the analyzing crystal, albeit, with some prevent wide selectability of line shape just by selection crystals and collimators. Since mechanical limitations wavelength range, depending upon the selection of one order of magnitude variation in the resolution of approximately 10–100 eV.

From the above, it will be clear that there is about one order of magnitude variation in the resolution of a wavelength-dispersive spectrometer over the usual wavelength range, depending upon the selection of crystals and collimators. Since mechanical limitations prevent wide selectability of line shape just by selection of collimator divergence, in practice, the resolution of the spectrometer will mainly be a function of the angular dispersion of the analyzing crystal, albeit, with some influence of the breadth of the diffracted line profile. It will be seen from Equation (3) that the angular dispersion will be high when the $d$-spacing is small. This is unfortunate as far as the range of the spectrometer is concerned because a small value of $2d/\lambda$ means in turn a small range of wavelengths coverable. Thus, as with the resolution and peak intensities, high dispersion can only be obtained at the expense of cutting down the wavelength range covered by a particular crystal. In order to circumvent this problem, it is likely that several analyzing crystals will be employed in the coverage of a number of analyte elements. Many different analyzing crystals are available, $^{(6)}$ each having its own special characteristics, but three or four crystals will generally suffice for most applications.

The output from a wavelength-dispersive spectrometer may be either analog or digital. Pulses from the detector are amplified and passed via the pulse height selector on to one of two circuits. For qualitative work an analog output is traditionally used and in this instance a rate meter is used to integrate the pulses over short time intervals, typically of the order of a second or so. The output from the rate meter is fed to an x/t recorder that scans at a speed that is synchronously coupled with the goniometer scan speed. The recorder thus displays an intensity/time diagram, which becomes an intensity/2$\theta$ diagram. Tables are then used to interpret the wavelengths. For quantitative work it is more convenient to employ digital counting and a timer/scaler combination is provided that will allow pulses to be integrated over a period of several tens of seconds and then displayed as count or count rate. In more modern spectrometers a scaler/timer may also take the place of the rate meter, using a process known as step-scanning. In this instance the contents of the scaler are displayed on the x-axis of the x/t recorder as a voltage level. The scaler/timer is then reset and then started for a selected time interval. At the end of this time the timer sends a stop pulse to the scaler that now holds a number of counts equal to the product of the counting rate and the count time. The contents of the scaler are then displayed as before, the goniometer stepped to its next position and the whole cycle repeated. Generally the process is completely controlled by a microprocessor or a personal computer.

5.4 Spectrometers for X-ray Fluorescence

Simultaneous wavelength-dispersive spectrometers were introduced in the early 1950s, and sequential systems about a decade later. At this time, about 30 000 or so wavelength-dispersive instruments have been supplied commercially, roughly one-third of these in the USA. Energy-dispersive spectrometers became commercially available in the early 1970s and today there are of the order of 20 000 units in use. The two major categories of wavelength-dispersive X-ray spectrometers differ mainly in the type of source used for excitation, the number of elements that they are able to measure at one time, the speed at which they collect data and their price range. For high specimen throughput quantitative analysis where speed is of the essence, and where high initial cost can be justified, simultaneous wavelength-dispersive spectrometers are probably the best. For more flexibility, where speed is important but not critical and where moderately high initial cost can be justified, sequential wavelength-dispersive spectrometers are probably the best. Both of the instruments are, in principle at least, capable of measuring all elements in the periodic classification from $Z = 9$ (F) and upwards, and most modern wavelength-dispersive spectrometers can do some useful measurements down to $Z = 6$ (C). Both can be fitted with multisample handling facilities and both can be automated by use of personal computers. Both are capable of precision of the order of a few tenths of 1% and both have sensitivities down to the ppm level. Single-channel wavelength-dispersive spectrometers are typically employed for both routine and nonroutine analysis of a wide range of products, including ferrous and nonferrous alloys, oils, slags and sinters, ores and minerals and thin films. These systems are very flexible but, relative to multichannel spectrometers, are somewhat slow. The multichannel wavelength-dispersive instruments are used almost exclusively for routine, high throughput analyses where there is need of fast accurate analysis, but where flexibility is of no importance.

While the various types of specialized X-ray spectrometers are not generally available to the average
user, they do have important roles to play in special areas of application. Included within this category are total reflection X-ray fluorescence (TRXRF) spectrometers and synchrotron source X-ray fluorescence (SSXRF) spectrometers. Two things that these systems have in common are a very high sensitivity and ability to work with extremely low concentrations and/or small specimens. The TRXRF system makes use of the fact that at very low glancing angles, primary X-ray photons are almost completely absorbed within thin specimens and the high background that would generally occur due to scatter from the sample support is absent. The recent development of high intensity synchrotron radiation beams has led to interest in their application for X-ray fluorescence analysis. The high intensity available in synchrotron beams allows use of very narrow band path monochromators between source and specimen, giving, in turn, a high degree of selective excitation. A compromise that must always be made in the design and set-up of any spectrometer is that between intensity and resolution, resolution being defined as the ability of the spectrometer to separate lines. In the flat-crystal wavelength-dispersive system this resolution is dependent upon the angular dispersion of the analyzing crystal and the divergence allowed by the collimators (Figure 3).

6 WAVELENGTH-DISPERSIVE SPECTROMETER

Wavelength-dispersive spectrometers employ diffraction by a single crystal to separate characteristic wavelengths emitted by the sample. Energy-dispersive spectrometers use the proportional characteristics of a photon detector, typically lithium-drifted silicon, to separate the characteristic photons in terms of their energies. Since there is a simple relationship between wavelength and energy, these techniques each provide the same basic type of information, and the characteristics of the two methods differ mainly in their relative sensitivities and the way in which data are collected and presented. Generally speaking the wavelength-dispersive system is roughly one to two orders of magnitude more sensitive than the energy-dispersive system. Against this, however, the energy-dispersive spectrometer measures all elements within its range at essentially the same time, whereas the wavelength-dispersive system identifies only those elements for which it is programmed. To this extent, the energy-dispersive system is more useful in recognizing unexpected elements. Both wavelength- and energy-dispersive spectrometers typically employ a primary X-ray photon source operating at 0.5 to 3 kW. A disadvantage with this type of source is that the specimen scatters the white radiation from the source leading to significant background levels that tend to become one of the major limitations in the determination of low concentration levels. Typical analysis times vary from about 10 s to 3 min per element. The minimum sample size required is of the order of a few milligrams, although typical sample sizes are probably around several grams. Good accuracy is obtainable and in favorable cases standard deviations of the order of a few tenths of 1% are possible. This is because the matrix effects in X-ray spectrometry are well understood and relatively easy to overcome. The sensitivity is fair and determinations down to the low ppm level are possible for most elements.

6.1 Sequential Spectrometers

A sequential spectrometer, often referred to as a scanning spectrometer, uses a single crystal and a single detector. A simultaneous spectrometer contains many crystal/detector sets which are used to measure elements simultaneously. Of these two basic types, the sequential systems are the most common. A typical sequential spectrometer system consists of the X-ray tube, a specimen holder support, a primary collimator, an analyzing crystal and a tandem detector. The gas flow counter is ideal for the measurement of the longer wavelengths and the scintillation counter is best for the short wavelengths. A portion of the characteristic fluorescence radiation from the specimen is passed via a collimator or slit onto the surface of an analyzing crystal, where individual wavelengths are diffracted to the detector in accordance with the Bragg law. A goniometer is used to maintain the required $\theta$ to $2\theta$ relationship between crystal and detector. Typically, six or so different analyzing crystals and two different collimators are provided in this type of spectrometer,
giving the operator a wide range of choice of dispersion conditions. In general, the smaller the 2d-spacing of the crystal, the better the separation of the lines but the smaller the wavelength range that can be covered. Since the maximum achievable angle \( \theta \) on a wavelength-dispersive spectrometer is generally around 73°, the maximum wavelength that can be diffracted by a crystal of spacing 2d is equal to about 1.9d. The separating power of a crystal spectrometer is dependent upon the divergence allowed by the collimators (which to a first approximation determines the width of the diffracted lines) and the angular dispersion of the crystal. Since mechanical limitations prevent wide selectability of line shape just by selection of collimator divergence, in practice, the resolution of the spectrometer is typically determined by the angular dispersion of the analyzing crystal, albeit with some influence of the breadth of the diffracted line profile.

### 6.2 Simultaneous Spectrometers

The simultaneous spectrometer is generally nothing more than a group (6–30) of fixed-channel spectrometers arranged round the irradiated specimen. This arrangement allows one to tailor-make each channel, just for the element for which it is being set, so, in principal, if one had a 30-channel simultaneous spectrometer, every crystal/collimator slit/detector combination could be different for each channel. It is common to use a curved crystal arrangement, as shown in Figure 4, since this is more efficient and requires only a very small detector window. The curved crystals may be simply bent, or bent and ground, or even may be formed as a section of a logarithmic spiral. The simultaneous spectrometer offers great speed and high specimen throughput – a sample containing 24 elements can be analyzed in less than 1 min. Against this, however, there is a loss in flexibility in comparison with the sequential spectrometer, and the equipment cost is higher – perhaps by a factor of two. Some flexibility can be regained by use of one or more scanning channels. These scanning channels are, in essence, the same as a conventional optical system in the sequential spectrometer.

### 6.3 Other Types of X-ray Spectrometer

#### 6.3.1 Energy-dispersive Systems (see Portable Systems for Energy-dispersive X-ray Fluorescence)

The energy-dispersive spectrometer consists of the excitation source and the spectrometer/detection system. The spectrometer/detector is typically an Si(Li) detector, which is a proportional detector of high intrinsic resolution. A multichannel analyzer is used to collect, integrate and display the resolved pulses. While similar properties are sought from the energy-dispersive system as with the wavelength-dispersive system, the means of selecting these optimum conditions are very different. Since the resolution of the energy-dispersive system is equated directly to the resolution of the detector, this feature is of paramount importance. The output from an energy-dispersive spectrometer is generally displayed on a cathode ray tube and the operator is able to dynamically display the contents of the various channels as an energy spectrum and provision is generally made to allow zooming in on portions of the spectrum of special interest, to overlay spectra, to subtract background, and so on. Even though the Si(Li) detector is the most common detector used in energy-dispersive X-ray spectrometry, it is certainly not the only one. As an example, the higher absorbing power of germanium makes it an alternative for the measurement of high-energy spectra. Both cadmium telluride (CdTe) and mercuric iodide (HgI₂) show some promise as detectors capable of operating satisfactorily at room temperature.

#### 6.3.2 On-stream Analyzers

The use of conventional and nonconventional wavelength-dispersive X-ray spectrometers for on-line process control has long been recognized, and currently there are several hundreds of these units in use. The major use is found in mineral beneficiation processes, although some units are used for the control of cement kilns. Essentially three major areas of application exist:
1. Analysis of flowing slurries found in most ore dressing and mineral beneficiation plants.

2. Analysis of flowing dry solids, for example, crushed ores on conveyor belts, or dry raw cement mix en route to the kiln.

3. Analysis of drill cores and insides of bore holes.

The first category is typically covered by a conventional wavelength-dispersive spectrometer, generally in a multichannel configuration, and using a specially designed flow cell in place of the regular fixed sample holder. A complex plumbing system is then required to effectively sample the flowing slurry, and inject it continuously into the flow cell. Because of the effect of absorption by the (thick) flow cell windows, and the necessary air path in the system, it is almost impossible to use this technique to determine elements below atomic number 22 (Ti). The second category can be handled by either continuous analysis or by successive sampling. Special care must be made in continuous analysis because of variations in particle size of the feed. An advantage of the successive sampling technique is that automated samplers, pellet presses and borax bead makers can all be employed to provide a rapid and reliable analysis for most of the atomic number range. The third category is covered mainly by the use of radioisotope-based systems. The major disadvantage of any on-stream analyzer based on a source/multichannel, crystal dispersion system is its high inherent cost and physical size, not to mention the amount of specimen to be analyzed resting in the plumbing required to bring the specimen to the analysis chamber. Many of these problems can be resolved by use of a radioisotope-based system, which can be small, compact, and relatively inexpensive. $^{8}$ Am$^{241}$, Cd$^{109}$, and Gd$^{153}$ have all been successfully employed as sources. The great disadvantage of the radioisotope source is that its total photon yield is small in comparison to conventional sealed-source X-ray tubes. In order to recover some of this inefficiency, it is common to use energy discrimination, rather than the classic dispersive crystal arrangement, in radioisotope-based systems.

6.3.3 Total Reflection Spectrometers

One of the major problems that inhibits obtaining good detection limits in small samples is the high background due to scatter from the sample substrate support material. The suggestion to overcome this problem by using total reflection of the primary beam was made long ago, but the absence of suitable instrumentation prevented real progress being made until the late 1970s. Good sample preparation and presentation procedures are now available, making TRXRF a valuable technique for trace analysis in which the Si(Li) detector is placed close to (about 5 mm), and directly above, the sample. $^{9}$ Primary radiation enters the sample at a glancing angle of a few seconds of arc. The sample itself is typically presented as a thin film on the optical flat surface of a quartz plate. A typical instrument contains a series of reflectors to aid in the reduction of background. A beam of radiation from a sealed X-ray tube passes through a fixed aperture onto a pair of reflectors that are placed very close to each other. Scattered radiation passes through the first aperture to impinge on the sample at a very low glancing angle. Because the primary radiation enters the sample at an angle barely less than the critical angle for total reflection, this radiation barely penetrates the substrate media; thus scatter and fluorescence from the substrate are minimal. Because the background is so low, picogram amounts can be measured or concentrations in the range of a few tenths of a part per billion can be obtained without recourse to preconcentration.

6.3.4 Use of Synchrotron Source Radiation

The availability of intense, linearly polarized synchrotron radiation beams $^{10}$ has prompted workers in the fields of X-ray fluorescence $^{11}$ to explore what the source has to offer over more conventional excitation media. In the synchrotron, electrons with kinetic energies of the order of several billion electron-volts (typically 3 GeV), orbit in a high vacuum tube between the poles of a strong (about $10^{4}$ G) magnet. A vertical field accelerates the electrons horizontally, causing the emission of synchrotron radiation. Thus synchrotron source radiation can be considered as magnetic bremsstrahlung in contrast to normal electronic bremsstrahlung produced when electrons are decelerated by the electrons of an atom. It has been found that because the primary source of radiation is so intense, it is possible to use a high degree of monochromatization between source and specimen, giving a source that is wavelength (and, therefore, energy) tunable, as well as being highly monochromatic. The intensity of the synchrotron beam is probably four to five orders of magnitude greater than the conventional bremsstrahlung source-sealed X-ray tubes. This, in combination with its energy tunability and polarization in the plane of the synchrotron ring, allows very rapid bulk analysis to be obtained on small areas. Because the synchrotron beam has such a high intensity and small divergence, it is possible to use it as a microprobe of high spatial resolution (about 10 µm). Absolute limits of detection around 10–14 µg have been reported using such an arrangement.

A good example of the power of synchrotron source radiation is found in the study of the thin film superconductors which are required for applications of high-temperature superconductors (HTSCs) in microelectronics technology. An example of such work $^{12}$
involves the analysis of HTSC films produced by laser evaporation of elements in the Y–Ba–Cu–O system. Ten films were simultaneously deposited with various target-to-substrate distances allowing study to be made of the laser plasma expansion in vacuo. A very important advantage of this method is that it allows extremely low detection limits to be achieved. As an example, in the referenced study the authors claim a detection limit of $5 \times 10^{13}$ atoms cm$^{-2}$. Additional advantages accrue because synchrotron radiation is highly polarized and background due to scatter can be greatly reduced by placing the detector at 90$^\circ$ to the path of the incident beam and in the plane of polarization.

7 QUALITATIVE ANALYSIS WITH THE X-RAY SPECTROMETER

Both the simultaneous (scanning) wavelength-dispersive spectrometer and the energy-dispersive spectrometers (see Portable Systems for Energy-dispersive X-ray Fluorescence) lend themselves admirably to the qualitative analysis of materials, since there is a simple relationship between the wavelength or energy of a characteristic X-ray photon and the atomic number of the element from which the characteristic emission line occurs. Thus by measuring the wavelengths, or energies, of a given series of lines from an unknown material, the atomic numbers of the excited elements can be established. The inherent simplicity of characteristic X-ray spectra makes the process of allocating atomic numbers to the emission lines relatively easy, and the chance of making a gross error is rather small. There are only 100 or so elements, and within the range of the conventional spectrometer each element gives, on average, only half a dozen lines. If one compares the X-ray emission spectrum with the ultraviolet (UV) emission spectrum, since the X-ray spectrum arises from a limited number of inner orbital transitions, the number of X-ray lines is similarly rather few. UV spectra, however, arise from transitions to empty levels, of which there may be many, leading to a significant number of lines in the UV emission spectrum. A further benefit of the X-ray emission spectrum for qualitative analysis is that because transitions do arise from inner orbitals, the effect of chemical combination or valence state is almost negligible.

Qualitative analysis has traditionally been performed by scanning the goniometer synchronously at a fixed angular speed. However, most scanning spectrometers are slow in this sequential angular/intensity data collection mode, not only because the data are taken sequentially, but also because in order to cover the full range of elements a series of scans must be made with different conditions. In addition to this, scanning at a fixed speed is somewhat inefficient because in the crystal dispersive system the atomic number varies as a function of one over the square root of the angle. In effect this means that in the low atomic number region much scanning time is wasted in scanning angular space that contains no characteristic line data. Although some unique designs have brought about some reduction in data acquisition times, this remains a major limitation of wavelength-dispersive spectrometers. Data interpretation involves identifying each line in the measured spectrogram. However, since the relationship between atomic number and Bragg angle is rather complicated, it is common practice to use sets of tables for interpretation relating wavelength and atomic number with diffraction angle for specific analyzing crystals. Some automated wavelength-dispersive spectrometers provide the user with software programs for the interpretation and labeling of peaks.

8 ACCURACY OF X-RAY FLUORESCENCE

Table 5 lists the four main categories of random and systematic error encountered in X-ray fluorescence analysis. The first category includes the selection and preparation of the sample to be analyzed. Two stages are generally involved before the actual prepared specimen is presented to the spectrometer, these being sampling and specimen preparation. The actual sampling is rarely under the control of the spectroscopist and it generally has to be assumed that the container containing the material for analysis does, in fact, contain a representative sample. It will be seen from the table that, in addition to a relatively large random error, inadequate sample preparation and residual sample heterogeneity can lead to very large systematic errors. For accurate analysis these errors must be reduced by use of a suitable specimen preparation method. The second category includes errors arising from the X-ray source previously discussed. Source errors can be reduced to less than 0.1% by use of the

</table>
ratio counting technique, provided that high frequency transients are absent. The third category involves the actual counting process and these errors can be both random and systematic. System errors due to detector dead time can be corrected either by use of electronic dead time correctors or by some mathematical approach. The fourth category includes all errors arising from inter-element effects. Each of the effects listed can give large systematic errors that must be controlled by the calibration and correction scheme.

8.1 Counting Statistical Errors

The production of X-rays is a random process that can be described by a Gaussian distribution. Since the number of photons counted is nearly always large, typically thousands of hundreds of thousands, rather than a few hundred, the properties of the Gaussian distribution can be used to predict the probable error for a given count measurement. There will be a random error \( \sigma(N) \) associated with a measured value of \( N \), this being equal to \( \sqrt{N} \). As an example, if \( 10^6 \) counts are taken, the \( 1\sigma \) standard deviation will be \( \sqrt{10^6} = 10^3 \), or 0.1%. The measured parameter in wavelength-dispersive X-ray spectrometry is generally the counting rate \( R \) and, based on what has been already stated, the magnitude of the random counting error associated with a given datum can be expressed as Equation (10):

\[
\sigma(\%) = \frac{100}{\sqrt{N}} = \frac{100}{\sqrt{Rt}}
\]  

(10)

Care must be exercised in relating the counting error (or indeed any intensity related error) with an estimate of the error in terms of concentration. Provided that the sensitivity of the spectrometer in counts per second per percent, is linear, a count error can be directly related to a concentration error. However, where the sensitivity of the spectrometer changes over the range of measured response, a given fractional count error may be much greater when expressed in terms of concentration.

In many analytical situations the peak lies above a significant background and this adds a further complication to the counting statistical error. An additional factor that must also be considered is that whereas with the scanning wavelength-dispersive spectrometer the peaks and background are measured sequentially, in the case of the energy-dispersive and the multichannel wavelength-dispersive spectrometers, a single counting time is selected for the complete experiment, thus all peaks and all backgrounds are counted for the same time. To estimate the net counting error in the case of a sequential wavelength-dispersive spectrometer it is necessary to consider the counting error of the net response of peak counting rate \( R_p \), and background counting rate \( R_b \), since the analyte element is only responsible for \( (R_p - R_b) \). Equation (10) must then be expanded to include the background count rate term to give Equation (11):

\[
\sigma(R_p - R_b) = \frac{100}{\sqrt{100 \sqrt{R_p} \sqrt{R_b}}} = \frac{100}{\sqrt{R_p - R_b}}
\]  

(11)

One of the conditions for Equation (11) is that the total counting time \( t \) must be correctly proportioned between time spent counting on the peak \( t_p \), and time spent counting on the background \( t_b \), as shown in Equation (12):

\[
\frac{t_p}{t_b} = \frac{R_p}{R_b}
\]  

(12)

8.2 Matrix Effects

In the conversion of net line intensity to analyte concentration it is necessary to correct for any absorption and/or enhancement effects which occur. Absorption effects include both primary and secondary absorption, and enhancement effects include direct enhancement, involving the analyte element and one enhancing element, plus third element effects that involve additional element(s) beyond the analyte and enhancer. Primary absorption occurs because all atoms of the specimen matrix will absorb photons from the primary source. Since there is competition for these primary photons by the atoms making up the specimen, the intensity/wavelength distribution of these photons available for the excitation of a given analyte element may be modified by other matrix elements. Secondary absorption refers to the effect of the absorption of characteristic analyte radiation by the specimen matrix. As characteristic radiation passes out from the specimen in which it was generated, it will be absorbed by all matrix elements, by amounts relative to the mass absorption coefficients of these elements. The mass absorption coefficient is a parameter which defines the magnitude of the absorption of a certain element for a specific X-ray wavelength. The total absorption of a specimen is dependent on both primary and secondary absorption. The total absorption by element \( i \) for an analyte wavelength \( \lambda_j \) is given by Equation (13):

\[
\alpha_i = \mu_i(\lambda) + A[\mu_i(\lambda_j)]
\]  

(13)

The factor \( A \) is a geometric constant equal to the ratio of the sines of the incident and take-off angles of the spectrometer. This factor is needed to correct for the fact that the incident and emergent rays from the sample have different pathlengths. The term \( \lambda \) in the equation refers to the primary radiation. Since most conventional X-ray spectrometers use a bremsstrahlung source, in
practice λ is a range of wavelengths, although in simple calculations it may be acceptable to use a single equivalent wavelength value where the equivalent wavelength is defined as a single wavelength having the same excitation characteristics as the full continuum.

There are a number of routes by which the analyte element can be excited or enhanced and these are illustrated in Figure 5(a) which shows the direct excitation of an analyte element \( i \) by the primary continuum \( P_1 \). There may also be excitation of the analyte by characteristic lines from the source (\( P_2 \) in Figure 5b). Both the continuous and characteristic radiation from the source may be somewhat modified by Compton scatter and the excitation by this modified source radiation is indicated in Figure 5(c) by \( P_3 \). Enhancement effects (Figure 5d) occur when a nonanalyte matrix element \( A \) emits a characteristic line that has an energy just in excess of the absorption edge of the analyte element. This means that the nonanalyte element in question is able to excite the analyte, giving characteristic photons over and above those produced by the primary continuum. This gives an increased, or enhanced, signal from the analyte. The third element effect is also shown. Here, a third element \( B \) is also excited by the source. Not only can \( B \) directly enhance \( i \), but it can also enhance \( A \), thus increasing the enhancing effect of \( A \) on \( i \). This last effect is called the third element effect.

Figure 5 Various routes by which characteristic analyte radiation can be excited. (Reproduced from R. Jenkins, X-ray Fluorescence Spectrometry, 2nd edition, John Wiley & Sons, New York, 1999, by permission of John Wiley & Sons, Ltd.)

8.3 Specimen Preparation for X-ray Fluorescence

Because X-ray spectrometry is essentially a comparative method of analysis, it is vital that all standards and unknowns be presented to the spectrometer in a reproducible and identical manner. Any method of specimen preparation must give specimens which are reproducible and which, for a certain calibration range, have similar physical properties including mass attenuation coefficient, density, particle size, and particle homogeneity. In addition the specimen preparation method must be rapid and cheap and must not introduce extra significant systematic errors, for example, the introduction of trace elements from contaminants in a diluent. Specimen preparation is an all important factor in the ultimate accuracy of any X-ray determination, and many papers have been published describing a multitude of methods and recipes for sample handling.\(^{13}\)

In general samples fit into three main categories:

1. Samples which can be handled directly following some simple pretreatment such as pelletizing or surfacing. For example, homogeneous samples of powders, bulk metals or liquids.
2. Samples which require significant pretreatment. For example, heterogeneous samples, samples requiring matrix dilution to overcome inter-element effects and samples exhibiting particle size effects.
3. Samples which require special handling treatment. For example, samples of limited size, samples requiring concentration or prior separation and radioactive samples.

The ideal specimen for X-ray fluorescence analysis is one in which the analyzed volume of specimen is representative of the total specimen, which is, itself, representative of the sample submitted for analysis. There are many forms of specimen suitable for X-ray fluorescence analysis, and the form of the sample as received will generally determine the method of pretreatment. It is convenient to refer to the material received for analysis as the sample, and that which is actually analyzed in the spectrometer as the specimen. While the direct analysis of certain materials is certainly possible, more often than not some pretreatment is required to convert the sample to the specimen. This step is referred to as specimen preparation. In general, the analyst would prefer to analyze the sample directly, because if it is taken as received, any problems arising from sample contamination that might occur during pretreatment are avoided. In practice, however, there are three major constraints that may prevent this ideal circumstance from being achieved: sample
size, sample size homogeneity and sample composition heterogeneity.

Problems of sample size are frequently severe in the case of bulk materials such as metals, large pieces of rock, etc. Problems of sample composition heterogeneity will generally occur under these circumstances as well, and in the analysis of powdered materials heterogeneity must almost always be considered. The sample as received may be either homogeneous or heterogeneous; in the latter case, it may be necessary to render the sample homogeneous before an analysis can be made. Heterogeneous bulk solids are generally the most difficult kind of sample to handle, and it may be necessary to dissolve or chemically react the material in some way to give a homogeneous preparation. Heterogeneous powders are either ground to a fine particle size and then pelletized, or fused with a glass-forming material such as borax. Solid material in liquids or gases must be filtered out and the filter analyzed as a solid. Where analyte concentrations in liquids or solutions are too high or too low, dilution or preconcentration techniques may be employed to bring the analyte concentration within an acceptable range.

9 QUANTITATIVE ANALYSIS

In the X-ray analytical laboratory the quantitative method of analysis employed will be typically predicated by a number of circumstances of which probably the four most common are: the complexity of the analytical problem; the time allowable; the computational facilities at the disposal of the analyst; and the number of standards available. It is convenient to break quantitative analytical methods down into two major categories: single-element methods and multiple-element methods, as shown in Table 6. The simplest quantitative analysis situation to handle is the determination of a single element in a known matrix. A slightly more difficult case might be the determination of a single element where the matrix is unknown. As shown in the table, three basic methods are commonly employed in this situation: use of internal standards, use of standard addition, or use of a scattered line from the X-ray source. The most complex case is the analysis of all, or most, of the elements in a sample about which little or nothing is known. In this case a full qualitative analysis would be required before any attempt is made to quantitate the matrix elements. Once the qualitative composition of the sample is known, again, one of three general techniques is typically applied: use of type standardization, use of an influence coefficient method, or use of a fundamental parameter technique. Both the influence coefficient and fundamental parameter technique require a computer for their application.

One of the problems with any X-ray spectrometer system is that the absolute sensitivity (i.e. the measured counts per second per percent) decreases dramatically as the lower atomic number region is approached (Figure 6). The three main reasons for this decrease are the reduction in the fluorescence yield with decrease in atomic number, the decrease in the absolute number of useful long wavelength X-ray photons from a bremsstrahlung source with increase of wavelength and, thirdly, the increase of absorption effects, generally with increase of the wavelength of the analyte line. The first two of these problems are inherent to the X-ray excitation process and to constraints in the basic design of conventional X-ray tubes. The third, however, is a factor that depends very much on the instrument design, and, in particular, upon the characteristics of the detector. The detector that is used in long wavelength spectrometers is typically a gas flow proportional counter, in which an extremely thin, high-transmission window is employed.

The great flexibility, sensitivity and range of the various types of X-ray fluorescence spectrometer make them ideal for quantitative analysis. In common with

all analytical methods, quantitative X-ray fluorescence analysis is subject to a number of random and systematic errors that contribute to the final accuracy of the analytical result. Like all instrumental methods of analysis, the potential high precision of X-ray spectrometry can only be translated into high accuracy if the various systematic errors in the analysis process are taken care of. The precision of a wavelength-dispersive system for the measurement of a single, well separated line is typically of the order of 0.1%, and about 0.25% for the energy-dispersive system. A good rule-of-thumb which can be used in X-ray fluorescence analysis to estimate the expected standard deviation \( \sigma \) at an analyte concentration level \( C \) is given by Equation (14)

\[
\sigma = K \sqrt{C + 0.1}
\]  

(14)

where \( K \) varies between 0.005 and 0.05. For example, at a concentration level \( C = 25\% \), the expected value of \( \sigma \) would be between about 0.025% and 0.25%. A \( K \) value of 0.005 would be considered very high quality analysis and a value of 0.05 rather poor quality. The value of \( K \) actually obtained under routine laboratory conditions depends upon many factors but with reasonably careful measurements a \( K \) value of around 0.02 to 0.03 can be obtained. The correlation between the characteristic line intensity of an analyte element and the concentration of that element is typically nonlinear over wide ranges of concentration, due to inter-element effects between the analyte element and other elements making up the specimen matrix. However, the situation can be greatly simplified in the case of homogeneous specimens, where severe enhancement effects are absent, and here, the slope of a calibration curve is inversely proportional to the total absorption \( \mu \) of the specimen for the analyte wavelength. In this instance the slope \( K \) of the calibration curve is taken as \( W/I \), where \( I \) is the line intensity and \( W \) the weight fraction of the analyte element. Thus, Equation (15) holds:

\[
W = \frac{I}{K\mu}
\]  

(15)

9.1 Single-element Techniques

Single-element techniques reduce the influence of the absorption term \( \mu \) in Equation (15), generally by referring the intensity of the analyte wavelength to a similar wavelength, arising either from an added standard or from a scattered line from the X-ray tube. In certain cases, limiting the concentration range of the analyte may allow the assumption to be made that the absorption value does not significantly change over the concentration range and the calibration curve is essentially linear.

This assumption is applied in the traditional type standardization technique.

9.2 Use of Internal Standards

One of the most useful techniques for the determination of a single analyte element in a known or unknown matrix is to use an internal standard. The technique is one of the oldest methods of quantitative analysis and is based on the addition of a known concentration of an element which gives a wavelength close to that of the analyte wavelength. The assumption is made that the effect of the matrix on the internal standard is essentially the same as the effect of the matrix on the analyte element. Internal standards are best suited to the measurements of analyte concentrations below about 10%. The reason for this limit arises because it is generally advisable to add the internal standard element at about the same concentration level as that of the analyte. When more than 10% of the internal standard is added, it may significantly change the specimen matrix and introduce errors into the determination. Care must also be taken to ensure that the particle sizes of specimen and internal standard are about the same, and that the two components are adequately mixed. Where an appropriate internal standard cannot be found it may be possible to use the analyte itself as an internal standard. This method is a special case of standard addition, and it is generally referred to as spiking.

9.3 Type Standardization

Provided that the total specimen absorption does not vary significantly over a range of analyte concentrations, and provided that enhancement effects are absent and that the specimen is homogeneous, a linear relationship will be obtained between analyte concentration and measured characteristic line intensity. Where these provisos are met, type standardization techniques can be employed. It will also be clear from previous discussion that by limiting the range of analyte concentration to be covered in a given calibration procedure, the range in absorption can also be reduced. Type standardization is probably the oldest of the quantitative analytical methods employed, and the method is usually evaluated by taking data from a well characterized set of standards, and, by inspection, establishing whether a linear relationship is indeed observed. Where this is not the case, the analyte concentration range may be further restricted. The analyst of today is fortunate in that many hundreds of good reference standards are commercially available. While the type standardization method is not without its pitfalls, it is nevertheless extremely useful and is especially useful for quality control type applications where a finished product is being compared with a desired product.
Special reference standards may be made up for particular purposes, and these may serve the dual purpose of instrument calibration as well as establishing working curves for analysis. As an example, two thin glass film standard reference materials (SRMs) specially designed for calibration of X-ray spectrometers are available from the National Institute of Standards and Technology in Washington as SRMs 1832 and 1833. They consist of a silica-based film deposited by focused ion-beam coating onto a polycarbonate substrate. SRM 1832 contains aluminum, silicon, calcium, vanadium, manganese, cobalt and copper, and SRM 1833 contains silicon, potassium, titanium, iron, zinc and rhodium. The standards are especially useful for the analysis of particulate matter.

9.4 Influence Correction Methods

It is useful to divide influence coefficient correction procedures into three basic types: fundamental, derived and regression. Fundamental models are those which require starting with concentrations, then calculating the intensities. Derived models are those which are based on some simplification of a fundamental method but which still allow concentrations to be calculated from intensities. Regression models are those which are semi-empirical in nature, and which allow the determination of influence coefficients by regression analysis of data sets obtained from standards. All regression models have essentially the same form and consist of a weight fraction term, \( W \) (or concentration \( C \)), an intensity (or intensity ratio) term, \( I \), an instrument-dependent term which essentially defines the sensitivity of the spectrometer for the analyte in question, and a correction term which corrects the instrument sensitivity for the effect of the matrix. The general form is shown in Equation (16):

\[
\frac{W}{R} = \text{constant} + \text{[model-dependent term]} \quad (16)
\]

where \( W \) is the weight fraction of the analyte and \( R \) is the ratio of the analyte intensity measured from a pure elemental standard to that of the analyte line intensity measured from the specimen, with each intensity corrected for instrumental effects.

The different models vary only in the form of this correction term. Table 7 shows several of the more important of the commonly employed influence coefficient methods. All of these models are concentration correction models in which the product of the influence coefficient and the concentration of the interfering element are used to correct the slope of the analyte calibration curve. The Lachance–Traill model\(^{15} \) was the first of the concentration correction models to be published. Some years after the Lachance–Traill paper appeared, Heinrich et al. suggested an extension to the Lachance–Traill approach\(^{16} \) in which absorbing and enhancing elements are separated as \( \alpha \)- and \( \beta \)-terms. These authors suggested that the enhancing effect cannot be adequately described by the same hyperbolic function as the absorbing effect. A thorough study of Lachance–Traill coefficients based on theoretically calculated fluorescence intensities shows that all binary coefficients vary systematically with composition. Both the Claisse–Quintin\(^{17} \) and Lachance–Claise\(^{18} \) models use higher order terms to correct for so-called crossed effects, which includes enhancement and third element effects. These models are generally more suited for very wide concentration range analysis.

<table>

\frac{W_i}{R_i} = K_i
\]
| Lachance–Traill (1966): \[
\frac{W_i}{R_i} = K_i + \sum_j a_{ij} W_j
\]
| Claisse–Quintin (1967): \[
\frac{W_i}{R_i} = K_i + \sum_j a_{ij} W_j + \sum_j \gamma_j W_j^2
\]
| Rasberry–Heinrich (1974): \[
\frac{W_i}{R_i} = K_i + \sum_j a_{ij} W_j + \sum_{k \neq j} \gamma_{ik} \left( \frac{W_k}{1 + W_i} \right)
\]
| Lachance–Claise (1980): \[
\frac{W_i}{R_i} = 1 + \sum_j a_{ij} W_j + \sum_{k \neq j} \sum_{l \neq j} a_{ijk} W_j W_k
\]

9.5 Fundamental Methods

Since the early work of Sherman there has been a growing interest in the provision of an intensity/concentration algorithm which would allow the calculation of the concentration values without recourse to the use of standards. Sherman’s work was improved upon first by the Japanese team of Shiraia and Fujino\(^{19} \) and later by the Americans Criss and Birks\(^{20} \) with their program NRLXRF. The same group also solved the problem of describing the intensity distribution from the X-ray tube. The problem for the average analyst in the late 1960s and early 1970s, however, remained that of finding sufficient computational power to apply these methods. In the early 1970s, de Jongh\(^{21} \) suggested an elegant solution in which he proposed the use of a large main-frame computer for the calculation of the influence coefficients, then use of a small minicomputer for their actual application using a concentration correction influence model. One of the problem areas remains that of adequately describing the...
intensity distribution from the X-ray tube. While software packages are available for fundamental type calculations using data obtained with the energy-dispersive system, one major drawback remains in their application system which uses a modified primary excitation spectrum. Most fundamental quantitative approaches in use today employ measured or calculated continuous radiation functions in the calculation of the primary absorption effect. Where sharp discontinuities or “breaks” in this primary spectrum occur, as in the case of the energy-dispersive system, the calculation becomes very complicated.

10 TRACE ANALYSIS

10.1 Analysis of Low Concentrations

The X-ray fluorescence method is particularly applicable to the qualitative and quantitative analysis of low concentrations of elements in a wide range of samples, as well as allowing the analysis of elements at higher concentrations in limited quantities of materials. The measured signal in X-ray analysis is a distribution of counting rate $R$ as a function of either 2θ angle (wavelength-dispersive spectrometers) or as counts per channel as a function of energy (energy-dispersive spectrometers). A measurement of a line at peak position gives a counting rate which, in those cases where the background is insignificant, can be used as a measure of the analyte concentration. However, where the background is significant the measured value of the analyte line at the peak position now includes a count rate contribution from the background. The analyte concentration in this case is related to the net counting rate. Since both peak and background count rates are subject to statistical counting errors, the question now arises as to the point at which the net peak signal is statistically significant. The generally accepted definition for the lower limit of detection (LLD) is the concentration equivalent to two standard deviations of the background counting rate. A formula for the LLD can now be derived as shown in Equation (17):\(^{122}\)

\[
\text{LLD} = \frac{3}{m} \frac{R_b}{I_b}
\]  

(17)

Note that in Equation (17) $I_b$ represents one half of the total counting time. The sensitivity $m$ of the X-ray fluorescence method is expressed in terms of the intensity of the measured wavelength per unit concentration, expressed in counts per second per percent. Figure 6 showed the sensitivity (excitation factor) of a wavelength-dispersive spectrometer and indicates that the sensitivity varies by about four orders of magnitude over the measurable element range when expressed in terms of rate of change in response per rate of change of concentration. For a fixed analysis time the detection limit is proportional to $m/\sqrt{R_b}$ and this is taken as a figure of merit for trace analysis. The value of $m$ is determined mainly by the power loading of the source, the efficiency of the spectrometer for the appropriate wavelength and the fluorescent yield of the excited wavelength. The value of $R_b$ is determined mainly by the scattering characteristics of the sample matrix and the intensity/wavelength distribution of the excitation source. From inspection of Equation (17) it will be seen that the detection limit will be best when the sensitivity is high and the background is low. Both the spectrometer sensitivity and the measured background vary with the average atomic number of the sample. While detection limits over most of the atomic number range lie in the low ppm range, the sensitivity of the X-ray spectrometer falls off quite dramatically towards the long wavelength limit of the spectrometer due mainly to low fluorescence yields and the increased influence of absorption. As a result, poorer detection limits are found at the long wavelength extreme of the spectrometer that corresponds to the lower atomic numbers. Thus the detection limits for elements such as fluorine and sodium are at the levels of hundredths of 1% rather than ppm. The detection limits for the very low atomic number elements such as carbon ($Z = 6$) and oxygen ($Z = 8$) are, however, very poor and are typically of the order of 3–5%.

10.2 Analysis of Small Amounts of Sample

Conventional wavelength-dispersive X-ray fluorescence spectrometers are generally designed to handle large specimens with surface areas of the order of several square centimeters, and problems occur where the sample to be analyzed is limited in size. The modern wavelength-dispersive system is especially inflexible in the area of sample handling, mainly because of geometric constraints arising from the need for close coupling of the sample to X-ray tube distance, and the need to use an airlock of some kind to bring the sample into the working vacuum. The sample to be analyzed is typically placed inside a cup of fixed external dimensions that is, in turn, placed in the carousel. This presentation system places constraints not only on the maximum dimensions of the sample cup, but also on the size and shape of samples that can be placed into the cup itself. Primary source energy-dispersive systems do not require the same high degree of focusing, and to this extent are more easily applicable to any sample shape or size, provided that the specimen will fit into the radiation-protected chamber. In some instances the spectrometer can even be brought to the object to be analyzed. Because of this flexibility,
the analysis of odd-shaped specimens has been almost exclusively the purview of the energy-dispersive systems. Where practicable, the best solution for the handling of limited amounts of material is invariably found in one of the specialized spectrometer systems. This is also generally true for the analysis of low concentrations. The TRXRF system is ideally suited for the analysis of small samples in those cases where the specimen can be dispersed as a thin film onto the surface of the reflector substrate. The high specific intensity synchrotron source offers sensitivities many times greater than the sealed X-ray tube source and because of the small beam divergence it is possible to obtain good signals from very small specimens.

The detection limits directly achievable by the X-ray fluorescence method generally lie in the low ppm range or, in absolute terms, a nominal detection limit of 0.1 to 0.01 µg on a thin film sample. In favorable cases, such as the transition elements, this limit may go to about 0.1 ppm, and in the most unfavorable case typified by the lower atomic number elements, to about 50 ppm. One of the special problems encountered in the direct analysis of water samples stems from the need to support the specimen under examination. Most conventional spectrometers irradiate the sample from below and the support film both attenuates the signal from the longer wavelength characteristic lines as well as introducing a significant “blank”. Absorption by air also becomes an important factor for the measurement of wavelengths longer than about 2 Å and the need to work in a helium atmosphere introduces further attenuation of the longer wavelength signals.

This article of the Encyclopedia explains that analytical chemistry is problem solving and provides a systematic procedure to follow that will increase the likelihood of successfully providing a solution to the problem. The problem solving process is shown in a simple flow chart diagram with amplification in the text.

1 INTRODUCTION

Analytical chemistry is about solving problems. As analytical chemists, that is what we do. When we can, we try to prevent the problem from occurring. Otherwise, we provide a solution. Whether we work in academia or industry, government or private consulting, we solve problems. In our experience, the novice analytical chemist, when given a sample or assigned a problem to solve, has a tendency to run immediately to the laboratory to use whatever expensive instrument is at hand. That is exactly the wrong thing to do! This article will explain why that is wrong and provide a systematic procedure to follow that will increase the likelihood of successfully providing a solution to the problem.

The guiding philosophy to this procedure is summarized in Figure 1, the Problem Solving Flow Chart. As you can see, it is a flow chart or decision tree. At each point, the option to recycle back is offered. These “loops” provide the opportunity to refine continuously the problem definition and the problem solving approach as new information is obtained. This is crucial to achieving success: never lose sight of the problem!

2 DEFINITION OF THE PROBLEM

Lewis and Clark, the famous early American explorers, could have been analytical chemists. The approaches they used during their expedition to find a Northwest Passage (1804–1806) were not too different from those that a modern analytical scientist might use to solve a challenging technical problem.

Lewis and Clark realized that a poor definition of their “Northwest Passage Problem” would at least prevent them from finding this long sought route to Western North America. Errors in setting their course, misreading the weather, choosing their method of transport, or misinterpreting the intentions of the people they encountered during their journey could also lead to tragedy for them and the members of their expedition. If they made a faux pas in any of these areas they would expend substantial effort, extra time, and perhaps lose their lives before they reached their destination and returned safely to St. Louis. The results of their quest might also be lost to other explorers who would help “solve the problem” of opening easily traveled routes through the Louisiana Purchase for further development.

In 1803, the fifty-year interest in North America, west of the Mississippi River, by United States President Thomas Jefferson culminated in two events. The first was the authorization of an expedition to the Pacific Ocean via the Missouri River and the second was the purchase of the Louisiana Territory from France. The expedition was led by Meriwether Lewis and William Clark. They returned in 1806 with the first map and scientific observations of the flora and fauna of the route up the Missouri, over the Rocky Mountains, and down the Columbia River to the Pacific. Only one member of the expedition was lost, Sergeant Charles Floyd. He died, most likely, from an infected appendix that had ruptured. (1)

(1)
of the United States. The extra care taken by Lewis and Clark as they planned their expedition certainly helped assure the success of their two-year adventure.

Analytical problem solving is no different. Defining the problem effectively when it is first presented assures that it will be solved more efficiently. The analytical chemist must be certain that she is solving the correct problem and not merely treating a symptom of the problem. For example, if we were faced with a number of drums containing ethoxylated alcohol that have bulging tops and bottoms we could solve the symptom of the problem (i.e. the bulging) by simply releasing the gas from the drums. While this solution eliminates the symptom, it does not deal with the fundamental cause of the bulging – the chemical reactions producing the gas. Without examining the problem more thoroughly for its underlying causes the analytical chemist has no way of developing a solution that can be used to prevent recurrence of the “Bulging Drums”.2

Careful definition of a problem’s scope and limiting conditions – time available, expense, safety, etc. – is an essential first step to effective problem solving. In the definition phase, the analytical scientist needs to describe the chemical and physical systems from which information must be obtained in order to meet technical and organizational objectives that require a solution to the problem.

The descriptions of the “chemical and physical systems” are much like the information that Lewis and Clark sought as they planned their journey. These descriptions answer the questions: Who? What? Where? When? and How? In the examples, the Bulging Drum and the Lewis and Clark Expedition, we might begin defining the scope of the problem by asking the following questions:

<table>
<thead>
<tr>
<th>Bulging Drum</th>
<th>Northwest Passage Expedition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Who discovered the drums?</td>
<td>Who has explored any territory west of St Louis?</td>
</tr>
<tr>
<td>What did this person observe when he found the drums?</td>
<td>What did these explorers see as they traveled west on the Missouri River?</td>
</tr>
<tr>
<td>Where were the drums found?</td>
<td>What are the conditions on the river?</td>
</tr>
<tr>
<td>What were the conditions?</td>
<td>When were portages encountered? Were they long or short?</td>
</tr>
<tr>
<td>When were they found? Was it hot or cold?</td>
<td>How does the terrain of these portages differ?</td>
</tr>
<tr>
<td>How do these drums differ from “normal” drums of this chemical?</td>
<td>How does the chemical inside the drums differ from “normal” material?</td>
</tr>
<tr>
<td>How does the chemical inside the drums differ from “normal” material?</td>
<td>How many rapids are there? Can keel boats navigate them or do we need canoes?</td>
</tr>
</tbody>
</table>

(The answers to these questions are the starting points for information gathering – the second stage of analytical problem solving that will be discussed shortly.)

It is also important when defining a problem to understand the “technical and organizational objectives” associated with it. These objectives also set some of the boundary conditions and a framework within

---

**Figure 1** Analytical problem solving flow chart.
which the problem must be solved. The technical and organizational objectives are often intertwined and hard to distinguish as separate. When Lewis and Clark started their journey, they set off with a “technical objective” of discovery and exploration: to catalogue plant and animal life in the Northwest Territory. President Thomas Jefferson, however, had an “organizational objective” for Lewis and Clark: to find an all water route to the western edge of the Louisiana Purchase and to establish relations with the Native American inhabitants. Clearly the solution to the problem of exploring the American Northwest had to accommodate both objectives if it were to be considered a success.

In analytical chemistry, technical objectives are typically intended to produce purely technical outcomes – develop a better compositional determination, lower the detection limit of a method, understand the chemistry responsible for the performance of a product, or find novel chemical leads that may be fruitful avenues for new products. These objectives appear somewhat removed from organizational objectives, yet the technical objectives are shaped by organizational goals. In many respects, the technical objectives are a subset of the organizational objectives.

Organizational objectives usually guide the direction of problem solving in industry. These objectives focus on meeting the needs of customers for a product that is novel, can be produced efficiently, performs consistently and safely, is legal, and can be purchased at an acceptable price.

3 INFORMATION GATHERING

This is the second step in analytical problem solving. It was also an important component of the Lewis and Clark journey – they had to plan an itinerary based on whatever information they could find about the land and water courses along their intended route west from St. Louis.

Sometimes, even with careful definition of a problem, preliminary exploration may be necessary. When Lewis and Clark reached the junction where the Marias River joins the Missouri River, they had to decide which of these was the Missouri. When scouting reports were inconclusive, Lewis set out with a small party up the north fork and Clark took his party up the south fork. Upon returning, both Lewis and Clark believed the south fork was the Missouri while every other member of the expedition believed the north fork to be the correct choice. Lewis and Clark were correct in choosing the south fork as the Missouri, but Lewis went ahead with a small expedition by land to look for the expected falls or the mountains. Due to the lateness of the season, this was almost an irrevocable decision.

Similarly, an analytical scientist may have to reconsider her approach to the problem as she gathers new information. The skilled analytical problem solver collects enough information to narrow the many possible approaches to solve the problem, so as to use the most effective few. This may require her to reset her course to reach the true solution – an explanation for production of the gas in the bulging drums and a plan to prevent future occurrences of the chemical reactions that were responsible.

The questions – Who? What? Where? When? How? and Why? – posed as the problem was defined are now revisited to tease out essential details of information that will guide the eventual selection of the analytical methods used to solve the problem.

A few of the plentiful information sources available to the analytical chemist are presented in Table 1. These sources are classified into three categories.

3.1 Problem Originator

The first, problem originator(s) – either the person(s) who found the problem or the person(s) who caused it – are rich with details about the problem. These people often have first hand, specific, information that no one else has seen or knows about. The challenge for the analytical problem solver, like a good criminal detective, is to extract all of the pertinent details from the problem originator. This may best be accomplished by actually inspecting the problem first hand with the originator, or by asking the originator to explain the chemical process and

equipment that produced the problem: “Did operators do anything differently when they filled the drums of ethoxylated alcohol that would cause them to bulge?” If the “originator” only discovered the problem and is not knowledgeable about all of the technical aspects of it, he may at least be able to refer us to a person who is more familiar with the situation. Also, don’t forget that the originator may be well aware of the organizational ramifications of the problem – the manufacturing plant must shut down, the gas in the bulged drums may pose a safety hazard, or the ethoxylated alcohol may be contaminated and should not be used to make detergent products. The problem originator is frequently the best source of a broad set of background information. That information becomes a foundation from which to build a better understanding of the problem using internal company sources or by consulting external sources of information. This background information is also useful in creating early hypotheses about the cause of the problem that can be tested as more details are collected.

3.2 Company Sources
Internal company sources are obviously the next place to search in order to add information about the problem – its chemistry, previous occurrences of the problem under similar conditions, analytical procedures used to obtain critical data about the substances involved, and possible experts in the technology who continue to work with it or may have moved on to other assignments, yet are still accessible. The utility of the other internal company sources listed in Table 1 generally decreases in the order they are presented. Company reports are usually easily obtained, although the amount of detail they contain and frequent lack of direct applicability to a problem may limit their value. Memoranda often deal with very specific situations that may be difficult to link to the problem at hand, and they may be difficult to locate except in the most far-reaching and robust corporate information management systems. Analytical methods are much like company reports; relatively easily available, often with an archive of previous versions, and fairly specific in their application. Finally, there are laboratory notebooks. While these are frequently archived for many years, and references to them come from reports and analytical methods, their content is often difficult to decipher and put to direct use in solving a problem, except in the best of cases.

3.3 External Sources
External sources of information and the means to access them, either in hardcopy or through the Internet, are generally well known to the practicing analytical chemist. This is certainly the case with primary and secondary published literature, standard analytical methods, and patents (Table 1). Identifying useful consultants to address a very specific problem is usually a longer term proposition since the consulting scientist must be located, their credentials verified, consulting agreements drawn up and consulting time arranged. All of this may take more time than is available to solve a problem. On the other hand, industrial experts may be readily identified and easily accessed, especially if they are in some way connected with the problem. In the case of the bulging drums, the manufacturer of the ethoxylated alcohol is knowledgeable about its chemistry and is probably interested in helping the customer solve the problem in order to keep the customer’s business. Contract research laboratories can also be rich sources of information. When a problem relates to health, safety of chemicals, occupational safety, the environment, and regulated substances like food and drugs, government agencies may be a preferred source of information. Finally, manufacturers of analytical instruments or suppliers of chemicals often have an applications department whose scientists may have worked on analytical problems similar to the one you need to solve. They may be willing to assist – it could lead you to purchase one of their instruments. However, that help may be provided in a circumspect manner so as not to divulge information that the instrument manufacturer has obtained during their work with another company.

Ideally, we would like to perform a very thorough search for information so that we turn up all possible leads that can point the way to a solution. However, we must always remember the boundary conditions that we uncovered when we defined the problem. They may necessitate very rapid information gathering so that we can move forward quickly to solve the problem. Said differently, we may need to identify two or three of the most promising leads very quickly so that they can be evaluated before we try to exhaustively identify all of the potential causes for a problem. We can always recycle back to look for new explanations for the problem if the first ones do not work out. Lewis and Clark certainly charted and recorded their course regularly, and, when necessary, adjusted it to travel westward as directly as they could.

The result of information gathering should be several hypotheses about the cause of the problem that can be tested experimentally. With these hypotheses in hand we can proceed to the next stage of the problem solving process – selection of appropriate analytical techniques that we apply either to confirm or refute our hypotheses.

4 CONSIDERATIONS IN SELECTING AN ANALYTICAL METHOD
We have now defined the problem, gathered and studied the available information, and perhaps redefined the
problem, so now it is time to begin thinking about the analytical method(s) we will use when we go to the laboratory. What are the issues that we must consider? More than likely, the first thing that came to mind was one of the “technical issues” such as lower detection limits of the method, so let’s address these issues first.

### 4.1 Technical Considerations

#### 4.1.1 Limit of Detection

One of the first factors you are likely to consider is the limit of detection (LOD) of a candidate method. The LOD is the lowest concentration or amount of analyte which produces a signal that can reliably be differentiated from the response obtained in the absence of analyte or from a blank. Clearly, this is a critical issue – a method with a LOD of 1% Zn in water won’t be very useful if your problem involves trace level Zn contamination in a lake. The LOD is generally defined as the amount of analyte producing a signal which is three times the noise level of an analyte-free blank (S/N = 3). At a S/N of 3, there is still significant uncertainty that data are valid, so we generally try to work at a S/N of at least 10 (the limit of determination). Inherent to the LOD, and often confused with it, is sensitivity, the analytical response per unit concentration of analyte (i.e. the slope of the calibration curve for the technique). Remember that a method with high sensitivity does not necessarily have a low LOD; LOD also includes the noise of the measurement. Figure 2 shows these terms graphically.

#### 4.1.2 Accuracy and Precision

These two terms are confused as often as sensitivity and LOD, but actually are easy to understand. Accuracy is just the difference between your measured result and the true or accepted value. In actual practice, the average (mean) of multiple determinations is compared to the accepted value; but what is the accepted value? This may come from another older, proven method, an industry standard method, or an “official” standard. Accuracy of final results will be no better than the accuracy of the standards used in calibrating the analytical method. There are two kinds of standards, primary and secondary, which can be used to calibrate a method. In addition, the accuracy of methods can be validated using a variety of reference materials including those from the US National Institute of Standards and Technology (NIST, formerly the National Bureau of Standards, NBS), specialty standards from organizations such as the Environmental Protection Agency (EPA), United States Geological Survey (USGS) and their non-US equivalents, as well as, industry organizations.

#### 4.1.3 Precision

Precision is the repeatability or reproducibility of a measured result for a set of replicate analyses of the same sample. Figure 3 shows the difference between accuracy and precision in a simple, graphical way and introduces additional terms – systematic and random error. Systematic errors give results that are skewed in

![Figure 2](image1.png)  
**Figure 2** An analytical calibration curve with annotations defining several analytical figures of merit.

![Figure 3](image2.png)  
**Figure 3** The difference between accuracy and precision.
one direction; random errors cause results to be high or low, randomly.

4.1.4 Selectivity

The complexity of the matrix of a sample is a critical factor as you consider the appropriate analytical method to use. The selectivity of a method is its ability to respond to the analyte of interest in preference to other substances in the matrix. In general, we prefer using methods with higher selectivity to increase the reliability of the analytical results. Interferences are these other substances in the sample to which the method responds.

The sample matrix is the material with which the analyte is physically associated and/or chemically bound. In addition to the number of different chemical species, the matrix can be complex in its physical state. As you see in Table 2, this is not a trivial concern.

Quantitatively determining an unknown analyte in an unfamiliar matrix is a more daunting task than determining a known analyte in a well understood or simple matrix. Note that the more complex the matrix of the sample, the more important the sampling step becomes. Unfortunately, sampling is not always in the direct control of the analytical chemist. It is therefore, very important that the sampling procedure used by the “customer” (the individual who first presented the problem) be understood and, perhaps, questioned.

Selectivity is a continuum from nonselective methods to those that are specific for an analyte. As you will see in the later articles of this encyclopedia, there are many ways to achieve the selectivity needed for a given measurement. Some of these include chemical reaction-based methods, including inorganic qualitative analysis and organic functional group analysis, electrochemistry, radioimmunoassay, and enzymatic analysis. Physical separation techniques such as solvent extraction, chromatography, volatilization, and precipitation can all be used to separate the analyte from interfering compounds in the sample. Additional approaches such as spectroscopy, coupled techniques [e.g. gas chromatography/mass spectroscopy (GC/MS)], and modern data reduction and manipulation (e.g. chemometric techniques including factor analysis, pattern recognition, partial least squares, etc.) may also provide selectivity.

4.2 Nontechnical Considerations

In addition to considering technical factors such as accuracy, LOD, etc. your choice of analytical method will depend on many nontechnical factors. Does your laboratory have access to the needed equipment? Are personnel available to run the method? How many samples will be analyzed and how often? Is this a one of a kind problem, requiring only a small number of determinations or will the method be installed in a quality control (QC) lab and used hourly? This is particularly important to consider if the method of choice is expensive to perform because of high reagent cost or waste disposal costs. How long does it take to perform the determination? If it takes a long time, but you only have to do it a few times, that is quite different from use of the method in a QC laboratory. If you only need to analyze a few samples, perhaps using a contract lab or borrowing/renting an instrument is more appropriate. Don’t forget that any method you choose must be safe to perform in your laboratory. Do you have the appropriate hood for a perchloric acid digestion, for example? Each of these must be considered before you are ready to move onto the implementation phase of the problem solving flow chart. Tables 3 and 4 provide more details on the cost and safety issues.

4.2.1 Equipment Availability

Hopefully your own lab has the needed capability, but if not it may be available within another laboratory of your company. If not, it can be acquired by borrowing, leasing or renting, or purchase. It may be faster and more cost effective to use a contract laboratory or arrange to use equipment at a nearby university, regional research

| Table 2 Different physical states of the sample matrix |
|----------------|--------------------------------------------------|
| State of matrix | Location of analyte                             |
| Solid           | Uniformly dispersed                              |

5 IMPLEMENTATION OF THE ANALYSIS

5.1 Planning

After an analytical method has been selected, it is necessary to plan for the implementation of the analysis. If any hazardous samples or reagents are involved, the appropriate safety procedures should be reviewed with the affected laboratory personnel. This is especially important if the hazard level and corresponding safety procedure fall outside the norm for the laboratory. In the example of the Bulging Drum, the laboratory did not routinely handle explosive gases. If the samples are being analyzed to comply with government regulations, those regulations should also be reviewed. If, for example, the samples are the result of a designed experiment, then not all samples may be available at the same time. The customer and the analytical laboratory may need to agree on whether the samples will be analyzed as they become available, or only when all samples are available. When limited amounts of sample are available for multiple analyses, it may be necessary to plan the order of analyses to maximize the available sample.

5.2 Preparation, Sampling, and Pretreatment

Preparation and sampling may be concurrent or sequential. Frequently they are concurrent when the sampling is done by someone other than the laboratory analyst. Sampling is a topic where communication between the analytical laboratory, the customer, and the person performing the sampling is crucial. The type of sampling is influenced by both the physical state of the material (solid, liquid, or gas) and the nature of the question being addressed. Random sampling might be appropriate to characterize the variability in a sample, while systematic sampling will be necessary to characterize properties as a function of time. If a representative sample from a large bulk quantity of material is required, all parties must agree on whom is responsible for reducing the sample size to the appropriate level. In the example of the Bulging Drum, quickly learning to sample gases was the first order of business for a laboratory that normally received liquids and solids. For the laboratory to provide the most useful interpretation of the results, a complete understanding of the origin of the samples is necessary. Solid samples frequently require dissolution, digestion, extraction, etc. to be in a form suitable for analysis. Each member of the problem solving team needs to remember that the goal is a solution to the problem and the result of the sampling process will define the scope of the information to be applied to a solution. Next, the required reagents, apparatus, and instruments must be assembled; then sample pretreatment can begin. This is also usually the first stage where chemical selectivity is applied. This can range from extraction from water at a controlled pH into an organic phase, to liquid chromatography as a precursor to gas chromatography. The type of pretreatment is also strongly dependent on whether the goal is preconcentration (increase the analyte to matrix ratio) or cleanup (removal of items that will interfere with the analysis).

5.3 Calibration, Standardization, and Analysis

Calibration and standardization first come into play in quantitative analysis. Any spectroscopic method of identification relies on a calibrated frequency or wavelength scale. Verification of this calibration should be a routine part of analytical laboratory operation. If an internal standard is used, it should be added as early as practical in sample preparation. Quantitative analysis to determine one or more components of the sample requires standards to be procured or synthesized. Deciding on the range of calibration can be done in an iterative method. This is consistent with the recycle option illustrated in Figure 1. Additional standards can be added if results for the samples fall outside the range of the initial calibration. For complicated and varying sample matrices, the method of standard addition may be preferable to additional pretreatment or separation during sample preparation. When samples are finally analyzed, it is often a very satisfying point for the problem solver. A more challenging point may be convincing the customer on the need for a blank and agreeing on the appropriate blank.

5.4 Data Reduction

Data reduction is usually a combination of the application of statistics to analytical chemistry and the calculation of concentration, mass, volume, etc. from
a measured response. Integrated microprocessors on analytical instruments and desktop computers have greatly reduced the tedium involved in the calculations for large amounts of data. It is still possible, however, to use the wrong formula in a spreadsheet and turn the most carefully obtained analytical information into wrong answers. When any analytical figure of merit, such as precision, LOD, etc., is reported, the method used to calculate the figure of merit should be included. This is especially important if a result is “None Detected” and the value of the LOD is to be used in further calculations.

6 INTERPRETATION OF RESULTS

One of the reasons for doing careful problem definition, information gathering, and method selection is to make interpretation of results straightforward. The best experiments have results that are easily understood in terms of a solution to the problem. In the example of the bulging drum, results obtained prior to the identification of hydrogen as the explosive gas are not easily understood. The detection of hydrogen gas is easily understood as an explosive gas, but not in terms of a solution to the problem. Only when identification of hydrogen gas is combined with the presence of sodium borohydride are the results easily understood from the standpoint of problem solution. The focus here has shifted from samples to problem solution. The complete interpretation of results should also have the total problem as its focus rather than the analyst or analytical laboratory. Remember, the problem solution is not the analytical result; the analytical result is the key to understanding and solving the problem.

7 COMMUNICATION OF RESULTS AND THEIR MEANING

We have now reached the bottom of the Problem Solving Flow Chart (Figure 1) and the solution to the problem, assuming the data collected has, in fact, led to results which make sense. If not, we must go back to an earlier step and start again. If we are satisfied with the results obtained by our analytical problem solving skills, we must communicate the results and their meaning to everyone involved in the problem. Without sharing the knowledge, the problem has not been solved! Unless the results are documented and circulated, filed, etc., your efforts have been wasted. The complete problem has not really been solved; the situation cannot be rectified. In the Bulging Drum example used earlier, the technical solution of the problem was determined to be hydrogen gas derived from sodium borohydride decomposition in the drums of ethoxylated alcohol that had slightly elevated water content and lower than expected pH. With this knowledge in hand, the analytical chemist can meet with the process engineers and supplier of the ethoxylate to discuss options concerning the borohydride. Perhaps it isn’t needed and the supplier won’t add it in the future. If that isn’t possible, perhaps the ethoxylate specifications can be modified to require lower water content or higher pH. Plant procedures might also be changed so that the ethoxylate is used sooner and stored at lower temperatures. If these changes aren’t made, why shouldn’t the problem recur? In addition, the complete story, from problem to analytical solution to process resolution needs to be documented in a form that can be located in the future.

If Lewis and Clark hadn’t documented their journey, how would successive explorers and settlers have gained anything from it? Unfortunately, because of Lewis’ suicide before the journals were prepared for publication, few did gain much from the expedition’s scientific observations for the next hundred years. It was not until 1904 that a complete edition of the journals was published.

A report in the company library, appropriately indexed for searching, is the logical answer. The company intranet might also be a repository for the information, and circulation of a brief summary to appropriate people is also a useful tool. Presentation of good analytical detective work (problem solving!) at company technical symposia is another great way to prevent similar problems from occurring in the future.

The bottom line: good laboratory work is wasted if the results are not documented and translated into information that can be used to deliver an organizational solution to the problem, as well as the technical solution.

ACKNOWLEDGMENTS

The material in this article is derived, in part, from a one day short course we have taught which has had as its aim, explaining industrial analytical chemistry, careers in said field, and analytical problem solving to undergraduate students. The authors acknowledge other present and past Procter and Gamble Company analytical chemists who contributed to the ideas expressed in this article through their participation as course instructors: Val Adams, Bonnie Charpentier, Margi Conditt, Linda Cooper, Dick DePalma, Matt Doyle, Chris Frank, Mark Greenberg, Anita Guy, Susan Lunte, Sandy
Murawski, Diane Parry, Larry Perkins, David Pilosof, Doug Raynie, Pamela Schofield, and Suzanne Tanguay. We also acknowledge Ted Logan, Joel Shulman, Grover Owens, Bob Wade, and Whit Wharton for their input and support.

Archaeological Chemical Analysis

A. Mark Pollard and Carl Heron
University of Bradford, Bradford, UK

1 Introduction

Archaeology is about people. In one of the leading introductory texts on the subject, Renfrew and Bahn\(^1\) state that archaeology is concerned with “the full range of past human experience – how people organized themselves into social groups and exploited their surroundings; what they ate, made, and believed; how they communicated and why their societies changed”. Archaeology has been called “the past tense of cultural anthropology”, but it differs crucially from anthropology in one respect – it is impossible in archaeology to interview the subjects, or to observe them directly in their everyday life. Inferences about past societies are made from the evidence recovered by archaeological excavation – sometimes material evidence in the form of surviving artifacts or structures, sometimes fortuitous evidence in the form of preserved associated biological material such as insect remains. Sometimes it is the soils and sediments themselves – their nature and stratigraphy – which provide the evidence, or add additional information by providing a context. Hence the occasionally acrimonious debates in archaeology about the effects of looting or the undisciplined use of metal detectors, where objects are removed from their contexts without proper recording and informational value is lost.

Although archaeology is a historical discipline, in that it reconstructs events in the past, it is not the same as history. If history is reconstructing the past from documentary sources, then 99.9% of humanities’ five million years of evolution is beyond the reach of history. Even in historic times, there is still a distinctive role for archaeology. Documentary evidence can provide evidence on the “big events” – famous people, battles and invasions, and the history of states, but such written sources are often biased. History is written by the literate, and usually by the victorious. It can obscure the past as well as illuminate it. In contrast, archaeology is generally the story of the common people – about how they lived and died.

It is the focus on material evidence in archaeology which creates the need for scientific approaches to the past. There is a necessity to extract the maximum possible information from the generally mundane collection of bones, stone tools, shards of broken pots, corroded metalwork, and biological assemblages which make up the vast bulk of archaeological finds. Trade routes are

by a thorough knowledge of the archaeological context, degradative processes, and material–environment interactions. Case studies span a wide range of elemental, isotopic, and molecular investigations with a bibliography comprising nearly 200 publications.

1 INTRODUCTION

Archaeology is about people. In one of the leading introductory texts on the subject, Renfrew and Bahn\(^1\) state that archaeology is concerned with “the full range of past human experience – how people organized themselves into social groups and exploited their surroundings; what they ate, made, and believed; how they communicated and why their societies changed”. Archaeology has been called “the past tense of cultural anthropology”, but it differs crucially from anthropology in one respect – it is impossible in archaeology to interview the subjects, or to observe them directly in their everyday life. Inferences about past societies are made from the evidence recovered by archaeological excavation – sometimes material evidence in the form of surviving artifacts or structures, sometimes fortuitous evidence in the form of preserved associated biological material such as insect remains. Sometimes it is the soils and sediments themselves – their nature and stratigraphy – which provide the evidence, or add additional information by providing a context. Hence the occasionally acrimonious debates in archaeology about the effects of looting or the undisciplined use of metal detectors, where objects are removed from their contexts without proper recording and informational value is lost.

Although archaeology is a historical discipline, in that it reconstructs events in the past, it is not the same as history. If history is reconstructing the past from documentary sources, then 99.9% of humanities’ five million years of evolution is beyond the reach of history. Even in historic times, there is still a distinctive role for archaeology. Documentary evidence can provide evidence on the “big events” – famous people, battles and invasions, and the history of states, but such written sources are often biased. History is written by the literate, and usually by the victorious. It can obscure the past as well as illuminate it. In contrast, archaeology is generally the story of the common people – about how they lived and died.

It is the focus on material evidence in archaeology which creates the need for scientific approaches to the past. There is a necessity to extract the maximum possible information from the generally mundane collection of bones, stone tools, shards of broken pots, corroded metalwork, and biological assemblages which make up the vast bulk of archaeological finds. Trade routes are
inferred from fragments of broken glass or pottery manufactured in one place but found in another. The economies of ancient cities are reconstructed from a study of the animal bones found on midden tips. In this respect, archaeology has much in common with modern forensic science – events, chronologies, relationships, and motives are reconstructed from a wide range of material remains. To set the scene for fresh recruits to the study of the science of archaeology, it is instructive to challenge new students to name a scientific discipline which has no relevance to modern-day archaeology. One can easily go through the scientific alphabet, from astronomy to zoology, and find many obvious applications. It is possible, of course, to carry out the same exercise in the social sciences, and also in engineering. Few disciplines exist which have no relevance or application in archaeology, and archaeology is therefore truly an interdisciplinary subject.

A comprehensive history of scientific analysis applied to the study of past people and materials has not been written. Caley(2–4) gives summaries of the early applications of chemistry to archaeology, and a review paper by Trigger(5) gives an overview of the relationship between archaeology and the physical and biological sciences. A collection of recent scientific studies, largely relating to museum objects, including dating, authenticity, metalwork, ceramics, and glass, can be found in the volume edited by Bowman.6 Many conference proceedings (especially those entitled Archaeological Chemistry, produced by the American Chemical Society7–11) contain a very wide range of chemical studies in archaeology. Of the several books covering the chemical aspects of archaeological science, Goffer12 gives a very broad introduction to archaeological chemistry, covering basic analytical chemistry, the materials used in antiquity, and the decay and restoration of archaeological materials. More recent publications include that of Pollard and Heron,13 which gives a basic introduction to instrumental chemical analysis followed by seven chapters of case studies, and the book by Lambert,14 which has eight chapters, each based on the study of a particular archaeological material.

This review examines the historical origins of the applications of chemical analysis within archaeology. It then discusses the types of problem that can be answered by such analyses, dividing them somewhat arbitrarily into those designed to elucidate processes acting on archaeological materials, and those designed to answer specific archaeological questions. Consideration is given to the particular problems caused to the analyst by archaeological materials. This is followed by a brief review of the applications of analytical chemistry to archaeology, classified by broad analytical technique.

2 THE HISTORY OF ANALYTICAL CHEMISTRY IN ARCHAEOLOGY

Chemistry can claim to have a longer relationship with archaeology than most other sciences, going back well into the eighteenth century. The range of materials studied has varied enormously, ranging from the more obvious archaeological finds such as obsidian, flint, glass, pottery, and metals, to those which survive only occasionally and under exceptional conditions, such as skin, hair, and (possibly) faint traces of blood on stone tools.

Many eminent chemists feature in the early history of the scientific analysis of antiquities, such as Klaproth (1743–1817), Davy (1778–1829), Berzelius (1779–1848), Faraday (1791–1867), Berthelot (1827–1907), and Kekulé (1829–1896). Klaproth determined the approximate chemical composition of some Greek and Roman coins, a number of other metal objects, and a few pieces of Roman glass.15 In producing compositional data on ancient materials, Klaproth had first to devise workable quantitative gravimetric schemes for the analysis of copper alloys and glass. He became Berlin’s first Professor of Chemistry, and it is fitting, therefore, that he can also be credited with the inception of archaeological chemistry.

The discovery of the ruins of the Roman cities of Herculaneum and Pompeii in 1594, and their subsequent “excavation” starting in 1709, ignited a passion for Neo-Classicism in Europe.16 By the mid-eighteenth century, Pompeii was an important stop on the European “Grand Tour”, and several of the Royal Houses of Europe were sponsoring systematic recovery of objects from the sites. In 1815, Humphry Davy published a paper on the examination of ancient pigments collected at Rome and Pompeii.17 In addition to evidence for natural pigments, he was also able to identify a synthetic pigment later to be called Egyptian Blue, formed by fusing copper, silica, and naturally occurring natron (sodium carbonate). A report by Diamond in 1847 includes a short contribution on a Roman pottery glaze studied by Michael Faraday, which provided the first indications of lead glaze in antiquity.18 Similarly, Kekulé carried out the analysis of an ancient wood tar composed, in part, of compounds with aromatic rings, the structure of which he subsequently proposed in 1865.

These early forays were largely devoted to satisfying curiosity and to the acquisition of basic knowledge about the nature of materials used in antiquity. As early as the mid-nineteenth century, however, Wocel suggested that correlations in chemical composition could be used to provenance or identify the source of archaeological materials, and even to provide relative dates for manufacture and use.19,20 During the 1840s, Göbel, at the University of Dorpat in Estonia, studied large numbers of copper alloy artifacts from the Baltic region, comparing them...
with known artifacts of prehistoric, Greek, and Roman date. He concluded that the Baltic artifacts were probably Roman in origin. This marked a progression from the study of individual objects to a consideration of assemblages. The French mineralogist Damour proposed that the geographical source of stone axes could be located by considering the density and chemical composition of a number of rock types, including jade and obsidian. He also exhorted archaeologists to work closely with specialists from other disciplines such as geology, zoology, and paleontology – a plea which is still heard today.

The appearance of the first appendixes of chemical analysis in major excavation reports represents the earliest systematic collaboration between archaeologists and chemists. Examples include the analysis of four Assyrian bronzes and a sample of glass in Layard’s *Discoveries in the Ruins of Nineveh and Babylon* published in 1853 and Schliemann’s *Mycenae* first published in 1878. So influential was this latter work that William Gladstone, the British Prime Minister, wrote the preface. The reports in both these works were overseen by John Percy, a metallurgist at the Royal School of Mines in London. Between 1861 and 1875, Percy himself wrote four major works on metallurgy that include significant sections on the early production and use of metals, and which remain key sources for those interested in “pre-Industrial” metal processing. An important aspect of this work was the realization that the benefit of using chemical analysis to elucidate the composition of archaeological material was not just one-way. Percy himself wrote that “Some of the results are, I think, both novel and important, in a metallurgical as well as archaeological point of view”.

Schliemann, referring to more than 2000 amber beads recovered from Mycenae, wrote “It will, of course, for ever remain a secret to us whether this amber is derived from the coast of the Baltic or from Italy.” Towards the end of the 19th century, Otto Helm attempted to source amber in one of the earliest systematic applications of chemistry to a specific problem in archaeology. Helm based his approach, in part, on the succinic (butanedioic) acid content of Baltic amber, but did not undertake a study of other sources of fossil resins in Europe. A full account of these investigations has been compiled by Beck, who published the results of an intensive study using infrared (IR) spectroscopy which successfully discriminated between Baltic and non-Baltic European fossil resins. It appears that the vast majority of amber finds throughout prehistoric Europe do indeed derive from the Baltic coastal region, implying the presence of long exchange routes at an early date.

As more archaeological objects were recovered, there was an increasing need for restoration and conservation, which demanded a better understanding of the decay mechanisms for a wide range of materials. The pioneer in this area was Friedrich Rathgen, who in 1888 established a laboratory at the State Museum in Berlin and later published the first book dealing with practical procedures for the conservation of antiquities, including electrolytic removal of corrosion products and the use of natural consolidants (pine resin and gelatin) in conservation. Thus was born archaeological conservation science, in which substantive chemical understanding of degradation processes, and how to stabilize or reverse them, is applied to an ever-increasing range of museum materials.

By the end of the nineteenth century, new ideas began to appear. In 1892, Carnot suggested that fluorine uptake in buried bone might be used to provide an indication of the age of the bone, although the method was not tested until the 1940s, when such studies were central to the detection of the famous Piltdown hoax. The chemical study of archaeological bone, especially human, and more recently teeth, has continued to be a principal interest of archaeological chemists. The chemical composition of the mineral fraction is related to factors such as diet, health status, and exposure to environmental toxins – information important to an understanding of the quality of life in past societies. The isotopic composition of the organic component is similarly related to diet and health, and differences between various components of the skeleton with different turnover rates have been linked to mobility. Obviously, the analysis of bone presents different challenges to the analysis of inorganic artifacts. In life, it is a living tissue which does not respond simply to changes in the chemistry of dietary intake – assimilation of essential and trace elements into bone mineral is governed by physiological factors, which therefore require a detailed knowledge of human biochemistry. After death, biochemical control ceases, and another regime with different laws takes over – that of geochemistry. The composition of buried bone is controlled by a great many factors which, again, are not simple. Thus, in order to study one of the most important and abundant materials in the archaeological record – bone – archaeological chemistry has had to become familiar with the vast and complex subject of biogeochemistry.

Occasionally – perhaps once or twice a century – an archaeological find is made which radically influences life, not least in terms of fashion, art, and architecture. The revelation of Pompeii in the latter part of the eighteenth century was one such event. The discovery of the tomb of Tutankhamun by Howard Carter in 1922 was another. Perhaps less globally influential, but certainly of great public interest, was the discovery in September 1991 of the well-preserved body of a man high up in the Ötztaler Alps on the Austrian–Italian border. Subsequent investigations recovered not just the body,
but also a large collection of his equipment, some of which was made from materials such as birch bark which rarely survive in normal archaeological contexts. A large program of scientific investigations was initiated, ranging from obvious questions such as the date of the remains, to the identification of the parasites associated with the body, and the manufacturing technology of his clothing and equipment. Radiocarbon dating of bone and tissue from the body, as well as fibers from his clothing, revealed a date of between 3350 and 3120 BC, placing him in the Neolithic Period of northern Italy. Chemical analysis of the surface of his copper alloy ax revealed it to be almost pure copper (better than 99% copper, with traces of arsenic and silver). This composition is one which is thought to be characteristic of the Neolithic/Bronze Age transition, traditionally dated to about 2500 BC. The shape of the ax, however, is one which would conventionally have been described as Bronze Age, and dated to about 2000 BC, more than 1000 years later than the actual date of the body. He was also carrying with him a small flint dagger, classically dated to the Neolithic. Such a find, unique in Europe, has shown us that we need to know more about the dating of the transition from the Neolithic to the Bronze Age. Above all, this study underlines the forensic nature of the scientific investigation of ancient material, involving not only archaeologists and forensic pathologists, but many other specialists.

3 THE ROLE OF CHEMICAL ANALYSIS IN ARCHAEOLOGY

The historical introduction in section 2 has identified the origins of many of the issues addressed by the application of analytical chemistry to archaeology. They can be divided into those projects which attempt to understand the processes acting upon archaeological material before, during, and after burial, and those which use chemical methods to derive information to answer specific questions of interest to archaeology.

3.1 Questions of Process

3.1.1 Degradative Processes

Most material which enters the archaeological record degrades until it ceases to be a recognizable entity. Molecular evidence may remain, but to all intents and purposes the object has disappeared. Exceptions to this rule in the main constitute the material evidence upon which archaeological inference is based. Some materials, such as stone, almost always survive degradative processes (although they may succumb to other processes such as translocation). Others, such as skin, hair, and organic fabrics, only survive in exceptional circumstances such as extremes of cold or dryness. Many materials, such as metals, glass, and some of the more resistant organic materials such as amber, will undergo some degradation, but are likely to survive in a recognizable and recoverable form. Biological hard tissue (e.g. bone, teeth, horn, shell) undergoes particularly complex patterns of degradation because of its composite nature.

Chemical and biological degradation processes are part of a wider phenomenon which is termed *taphonomy*, originally defined as the process of transition of an organism from the biosphere to the lithosphere. It includes all natural and anthropogenic processes which create death assemblages before deposition, as well as those chemical, physical, and biological processes which act on the assemblage after deposition. It is also possible to conceive of the postdepositional “taphonomy” of nonbiotic material, e.g. metal and ceramic artifacts, since they too experience change as a result of environmental interaction, although this goes well beyond the original definition.

Analytical chemistry has a fundamental role to play in helping to understand some of the major aspects of taphonomic change. Some processes are likely to be primarily chemical in nature, such as the electrochemical corrosion of a metal object in an aqueous environment, although even here microbiological mediation is likely to be important. Some processes are structural, such as mineralogical changes taking place in ceramics as a result of interaction with groundwater. Others, such as the degradation of organic materials, may be largely biological, although chemical hydrolysis may also have an important role. Whatever the driving force, analytical chemistry is essential as a means of measuring, monitoring, modeling, and verifying these processes.

3.1.2 Material – Environment Interactions

The objective of understanding degradative processes is to improve our knowledge of the factors which control the preservation of archaeological evidence in the burial environment. The potential for survival is governed largely by the interaction of the material with its depositional environment. This process forms part of a continuum between the degradation of very recent material (perhaps a few months to years), knowledge of which may have forensic interest, the behavior of archaeological deposits (few tens of years up to tens of thousands), and ultimately to material of geological and paleobiological interest (hundreds of thousands to millions of years). There is little systematic understanding of the factors which control preservation for the wide range of materials encountered archaeologically, and
even less in the way of predictive models. Soil pH and Eh are often referred to as the “master variables” in the consideration of soil chemistry.\(^{41}\) However, their measurement in the field is not always easy or even possible because of fluctuating conditions. Moreover, the chemical composition of the soil water is a complex interaction of the mineralogical, organic, and atmospheric composition of the soil, further complicated by speciation, redox, and solubility factors within the soil solution.\(^{42}\) Again, direct measurement in the field is often impossible. Nevertheless, knowledge of such factors is vital for understanding the chemical environment of buried archaeological objects. In response to this, a whole family of groundwater geochemical modeling programs has been developed over the last 30 years.\(^{43}\) These programs allow speciation to be calculated for given total ion concentrations under specified conditions and the behavior of particular mineral species in contact with defined waters to be modeled, enabling the stabilities of such systems and their response to environmental change to be predicted. It is clear that this is the necessary point of departure for modeling the behavior of archaeological objects in contact with soil water and groundwater, but little has yet been done.

### 3.1.3 Conservation Science

The term “conservation science” includes characterization of the constituent materials and production techniques of objects produced by humans, the study and understanding of decay processes, and the study and evaluation of conservation products and techniques.\(^{44}\) It is generally taken to include all materials which might be put into a museum, such as ethnographic material and objects of industrial and military interest, as well as more conventional museum exhibits. It also includes issues surrounding the environmental monitoring of display conditions, impact of visitor numbers, and the like.\(^{45}\) Chemistry is generally at the heart of the conservation process, since the first step in conservation is to stabilize the object by preventing any further degradation. This requires an understanding of the composition of the object itself, and also the mechanisms by which such objects degrade, which usually requires microstructural analysis, or the analysis of corrosion products. In the museum context, nondestructive (or quasi-nondestructive techniques) such as X-ray fluorescence (XRF) are often preferred for the analysis of objects, although microanalysis by inductively coupled plasma mass spectrometry (ICPMS) or neutron activation analysis (NAA) is of importance, with Raman spectrometry (RS) and IR spectrometry being used for structural information and the identification of corrosion products.

### 3.2 Archaeological Questions

#### 3.2.1 Identification

Perhaps the simplest question that can be answered chemically is “what is this object made from?” The chemical identity of many archaeological artifacts may be obscured for a number of reasons. Simply, it may be too small, corroded, or dirty to be identified by eye. Furthermore, it may be made of a material which cannot be identified visually, or by simple (nondestructive) field tests. An example might be a metal object made of a silvery colored metal. It may be silver or a silver-rich alloy (in which case the precise composition may well carry information on debasement, which relates to economic history), but it may be an alloy designed to deceive, such as “nickel silver” (cupronickel alloys, such as are used in modern “silver” coinage). Conceivably, it might consist of some more exotic silvery metal, such as platinum, but this would excite great interest if identified in a European context prior to the mid-eighteenth century AD since this metal was supposedly unknown in Europe before then.

Thus, even the simple identification of a material may have important ramifications. In general, the required levels of analysis are relatively simple, subject to the usual constraints of archaeological materials. One preferred technique for many years has been XRF, because of its nondestructive nature (providing the sample can fit into a sample chamber), its restricted sample preparation requirements, and its multielement capability. During the 1960s an air path machine was developed specifically to allow the nondestructive analysis of larger museum objects,\(^{46}\) and since then there have been attempts to devise a portable XRF system to use in museum displays or at an archaeological excavation, as well as for geological purposes.\(^{47}\)

Identification of organic materials in archaeological contexts can pose more problems. Instances of identification of amorphous organic residues (either visible or occluded in another matrix) are addressed next. An example of a situation where the identification of the organically derived raw material used to manufacture artifacts is important is the discrimination between jet, shale and various forms of coal. Until 25 years ago, the classification of small pieces of jewelry made from various black materials was carried out by eye using a number of simple criteria such as color and structure.\(^{48}\) Although there is little difficulty when applying these techniques to geological hand specimens, the small size of most archaeological finds and the nature of the destructive sampling such as thin sectioning or even streak testing often renders such judgments difficult to make. Such identifications are, however, rather important because of the restricted number of geological sources of jet. In the British Bronze Age, for example, if a piece of jet is identified in a Wessex burial
context in southern England, then it is taken as evidence of trading links with Whitby on the northeastern coast (approx. 400 km distant), since this is the only significant source of jet in England. Other similar materials, such as shales and the various workable types of coal, are more widely distributed. Analytical work, initially by NAA and then using XRF, showed that inorganic composition could be used to partially discriminate between these sources, and also showed that many of the original attributions were likely to be incorrect. Subsequent work has refined the procedures, and most recently further progress in characterizing such material has been made using pyrolysis/gas chromatography/mass spectrometry (Py/GC/MS). Hindsight suggests that, given the nature of such materials, the use of organic analysis techniques may have yielded an earlier solution to the problem, but the approach taken reflects the trajectory of analytical work in archaeology, starting from studies of inorganic materials.

### 3.2.2 Provenance

As noted in section 2, the idea that the chemical composition of an archaeological artifact might be related to the geological source of the raw materials originated in the nineteenth century. Interestingly, this appears to be many years in advance of the development of the same idea in geochemistry. Quantitative study of the partitioning behavior of the elements between iron-rich and silicate-rich phases in the Earth’s crust was carried out in the first half of the twentieth century and resulted in the geochemical classification of the elements as lithophile and siderophile. Much of this early work was summarized by Goldschmidt in his seminal work on geochemistry. It was really not until this theoretical basis had been established that the concept of chemical provenance using trace elements acquired currency in geochemistry.

Perhaps an explanation of this can be found in the fact that the idea of provenance (based on stylistic or other visual characteristics) has a long history in archaeology, going back to at least the eighteenth century. In the absence of any scientific means of dating artifacts in museum and private collections, a great deal of attention was paid to the observation of stylistic development, and the search for “parallels” in other collections. These effectively gave a relative chronology for a particular set of objects, and allowed proposals to be made about where certain objects might have originated, if they were deemed to be “exotic”, or “imports”. It is not unexpected, therefore, that with the advent of instrumental methods of analysis (primarily optical emission spectroscopy (OES), in the 1920s), the composition of an object was added to the list of characteristics which might be used to indicate either the provenance of the object (taken here to mean the place of manufacture), or the position of an object in some evolutionary sequence of form or decoration. Thus were born the great ambitious programs of analytical studies of ancient artifacts, perhaps typified by the Stuttgart program for the analysis of European Bronze Age metalwork during the 1950s. Subsequently the analyses of other materials such as faience beads and ceramics were incorporated into analytical programs. During the second millennium BC, faience (sintered and glazed quartz) beads were distributed across prehistoric Europe, and they were thought to represent the contact of the more “barbarian” areas of Europe with the more advanced technologies of the Near East. In 1956 Stone and Thomas reported on the use of OES to “find some trace element, existent only in minute quantities, which might serve to distinguish between the quartz or sand and the alkalis used in the manufacture of faience and glassy faience in Egypt and in specimens found elsewhere in Europe”. Initial results suggested that OES data could not unequivocally distinguish between British and Near Eastern sources, but statistical re-evaluation suggested a British origin for the beads found in England and Scotland on the basis of the quantities of tin, aluminum, and magnesium present. This was significant, because it suggested independent evolution of manufacturing technology, rather than long-distance trade.

The “New Archaeology” of the 1960s, emphasizing as it did explicit relationships between material culture and human behavior, rejuvenated interest in scientific research into prehistoric trade and exchange. Invasion or diffusion of peoples was no longer viewed as the principal instigator of cultural change, but rather internal social processes. Evidence for social contact arising from exchange of artifacts and natural materials (as well as the transmission of ideas) was seen as important information in this debate, and one which scientific analysis might help evaluate. This initiated a golden era in archaeological chemistry, in which a wide range of scientific techniques were deployed in the hope of chemically characterizing materials such as obsidian, marble, ceramics, metals, glass, and natural organic materials including amber. These characterization studies were aimed at “the documentation of cultural contact on the basis of hard evidence, rather than on supposed similarities of form”. Perhaps most successful over the years has been the chemical characterization of ceramics, which has been mainly carried out by NAA. As an indication of the geographical and temporal spread of such research, recent studies have included Islamic pottery from medieval Cairo, Classic period pottery from the US Southwest, Iron Age pottery from South Africa, Chinese and European red stonewares, and Roman glazed ceramics and Greek and Cypriot pottery from the Classical world.
Scientific characterization studies remain an important research area in archaeology, utilizing a range of trace element compositions as determined by increasingly sensitive analytical instrumentation, but now also including biomarker compositions and isotopic measurements. Despite the increasing sophistication of the analytical techniques, the fundamental limitations of the process must, however, be remembered. In order to be successful, the project requires carefully chosen samples to answer a well-constructed archaeological question, which in turn must be securely based on an appropriate archaeological model of the situation. Even if the archaeological side of the problem is well defined, there remain limitations as to what can be achieved. In his review of chemical characterization, Harbottle\(^{67}\) reminded practitioners that:

"with a very few exceptions, you cannot unequivocally source anything. What you can do is characterize the object, or better, groups of similar objects ... and also characterize the equivalent source materials, if they are available, and look for similarities to generate attributions. A careful job of chemical characterization, plus a little numerical taxonomy and some auxiliary archaeological and/or stylistic information, will often do something almost as useful: it will produce groupings of artifacts that make archaeological sense. This, rather than absolute proof of origin, will often necessarily be the goal."

### 3.2.3 Manufacturing Technology, Date, and Authenticity

Another subset of questions which can be meaningfully addressed via chemical analysis relates to the determination of the technology used to produce an object. Often manufacturing technology can be adequately determined by careful visual and microscopic examination of the object, although experience has shown that laboratory or field simulations of ancient technologies are essential in order to fully understand ancient technologies, and can reveal some unexpected results.\(^{68}\) Occasionally, however, chemical analyses are required, either of the object itself, or sometimes of the waste material from the process, such as the vast quantities of vitreous slag produced during iron manufacture. In this case a knowledge of the purity of the iron produced, the composition of the waste slag, and the composition of any residual slag included in the metal can be combined to give an understanding of the general nature of the technology involved (e.g. bloomery or blast furnace), as well as a more detailed knowledge of the operating conditions of the process.\(^{69}\)

Given the increasing interest in our industrial heritage, and the resulting pressures to extend the legal protection and public explanation of its monuments, it is becoming more important to improve our understanding of the technological processes involved, including those from our recent past, some of which are now all but extinct.

Experience has shown that even contemporary literary and patent evidence cannot always be taken as reliable, as has been shown by studies of the post-Medieval European brass industry. The traditional method for the manufacture of brass is known the "calamine process", introduced into Europe by the Romans. This is a small-scale procedure carried out in a sealed crucible, in which small lumps of copper metal are mixed with calamine (taken to be zinc carbonate or the roasted form, zinc oxide) and heated with charcoal. The zinc vapor is absorbed by the copper before it melts, therefore producing brass by a solid–vapor reaction. The more modern process is called the direct process, and involves mixing metallic zinc with molten copper. Because of thermodynamic restrictions in the calamine process, the maximum uptake of zinc into the brass alloy is limited to around 28–30%, whereas the direct process can be used to give any desired alloy of copper and zinc. Thus the chemical analysis of a brass object can be used to give an indication of the process by which it was made, and also some idea of date – European brass with more than 30% zinc is taken to be a product of the direct process, and therefore implicitly to date from some time after the introduction of that process into Europe. Extensive analyses of well-dated objects including scientific instruments and coinage has shown, however, that the British patent to manufacture brass by the direct process, dated 1738, was taken out some time after the actual introduction of the process into western Europe, which was probably around 1650.\(^{13}\)

This rather crude analytical test to distinguish between manufacturing processes for brass is somewhat unsatisfactory, and cannot distinguish between calamine brass and brass made by the direct process but containing less than 30% Zn. There has been considerable interest in recent years in the possibility that certain high-temperature anthropogenic metal-producing processes might introduce measurable isotopic fractionation into the product.\(^{70}\) Early interest concentrated on lead, and more recently on copper,\(^{71}\) but theoretical studies and experimental observations on zinc have demonstrated for the first time that anthropogenic processes in brass manufacture might introduce sufficient differential isotopic fractionation of the zinc to allow the processing methodology to be distinguished.\(^{72}\) If verified by high-precision measurements, this observation has not only archaeological significance, but also wider implications for environmental geochemical monitoring.

The example of brass illustrates how the determination of manufacturing technology (by chemical or perhaps isotopic analysis) can also give an indication of the date of manufacture. More specifically, it gives an indication of a date before which a particular object could not have been manufactured, providing our understanding of the
appropriate ancient technology is accurate. This leads directly into the complex and sometimes controversial field of authentication of ancient objects, in which chemical analysis plays a large role. Thus any European brass object shown by analysis to contain more than 30% Zn must be dated to some time after the introduction of the direct process into Europe (remembering the uncertainty in the actual dates involved). This might be an extremely important consideration when judging the authenticity of a potentially valuable brass object. Perhaps the most famous example of authentication of a brass object is that of the “Drake Plate”, so called because it was said to have been left by Sir Francis Drake to claim the San Francisco Bay area in the name of Queen Elizabeth I of England, dated to June 17, 1579. Analysis of the plate(73) by XRF showed it to have a very high zinc content (around 35%), with very few impurities above 0.05%. This was quite unlike any other brass analyzed from the Elizabethan period, which typically had around 20% zinc and between 0.5% and 1% each of tin and lead. It was therefore adjudged unlikely to be of Elizabethan manufacture (a view supported by that fact that it had a thickness consistent with the No. 8 American Wire Gage standard used in the 1930s, when the plate first appeared). In fact, European brass was imported into North America during the first half of the seventeenth century, and there have been several very successful analytical studies using the composition of such objects to map relationships between native North Americans and the early European traders. (74)

A wide range of archaeological materials has been subjected to authenticity studies. (75) Where possible, this takes the form of a direct determination of the date of the object, such as by radiocarbon dating for organic materials or thermoluminescence analysis for ceramics and the casting cores of cast objects. For metal objects in particular, it has of necessity taken the form of chemical analysis and comparison with reliably dated objects from the same period. Coins have been particularly subjected to such studies, since the variations in fineness for precious metal coinage can give a reasonably reliable calibration curve by which to date or authenticate other coins, and also because the fineness of the precious metals in circulation can give a great deal of information about the economic conditions prevalent at the time. (76) Authenticity has been a particular concern for all the major museums in the world, and most have facilities for carrying out a number of tests similar to those described here before making any acquisition. Considerably more questionable is the situation with respect to the commercial trade in antiquities, where access to scientific laboratories willing to carry out authentication on objects of undefined provenance has been partially blamed for encouraging the uncontrolled looting of some of the richest archaeological sites in the world. (77)

3.2.4 Chemical Analysis of Human Remains

The closest we can ever come to the physical presence of our ancestors is to excavate and study human bone, and it is therefore natural that the scientific study of human remains should be accorded special status in modern archaeological research. The well-known saying “you are what you eat” has been taken almost literally in archaeology for the last 20 years, and reconstruction of long-term dietary averages has been attempted using trace element levels in bone mineral and stable isotope studies on collagen and mineral in both bone and teeth. (78) Early on in this work it became apparent that inorganic trace element studies in bone were potentially bedeviled by post mortem diagenetic effects, the magnitude and significance of which continue to be debated. (79–83) Isotopic studies have been analytically far less controversial and, for Holocene material at least, appear to avoid most of the diagenetic problems encountered with trace elements. (84) Most authors conclude that if some collagen survives in a molecularly recognizable form, then the isotopic signal measured on this collagen is unchanged from that which would have been measured in vivo. There are several reviews of dietary reconstruction using isotopic measurements on bone collagen, (85–88) bone lipid (89) and bone and dental carbonate. (90) The chemical study of the protein and mineral fractions of archaeological bone and teeth can therefore reveal information on diet and health, providing that our knowledge of living bone metabolism is adequate, and that we can account for the changes which may occur during burial. Both of these factors provide significant scientific challenges to archaeological chemists.

The isotopic method of dietary reconstruction is based on the observation that carbon and nitrogen isotope ratios \( ^{13}\text{C}/^{12}\text{C} \) and \( ^{15}\text{N}/^{14}\text{N} \) in bone collagen (and carbon in bone mineral carbonate) can reflect the corresponding isotopic ratios in the diet. (34) In principle these ratios can be used to distinguish between a reliance on terrestrial and on marine food resources in the diet of prehistoric humans. Carbon isotope ratios may further be used to differentiate between the consumption of terrestrial plants which photosynthesize using the \( \text{C}_3 \) pathway and of those using the \( \text{C}_4 \) pathway. Virtually all land plants photosynthesize using the \( \text{C}_3 \) pathway, but a few plants, mainly tropical grasses, have evolved the \( \text{C}_4 \) pathway as an adaptation to a hot dry environment. Archaeologically the most important \( \text{C}_4 \) plant is maize, which has its origins in central America, and carbon isotope measurements on human bone have been used with great success to
plot the spread of maize agriculture in prehistoric North American cultures. The nitrogen isotope ratios in bone predominantly reflect the importance of marine inputs into the diet, but can also reflect the differential utilization of nitrogen-fixing terrestrial plants (legumes) and non-nitrogen-fixing plants. These models of isotopic ecology have also been applied to modern terrestrial and marine ecosystems, and have been shown to have great value as ecological markers, as well as having significant archaeological implications.

One significant recent development is the observation that, because different parts of the skeleton are resorbed and remodeled at different rates during life, the isotopic (and potentially the trace element) composition of different skeletal elements might reflect changes in diet with time. More specifically, permanent dental tissue in humans is formed during early life (up to about 18 years of age) and then is chemically unchanged in adulthood. Bone, on the other hand, is constantly remodeled during life, and although there are differences of opinion about the rate at which different skeletal components remodel, it is true to say that for a mature individual the rib isotopic composition (for example) should reflect the average diet over the last few years of life. If the location of a particular individual changes, such that the dietary balance is altered significantly, then this might be apparent from a chemical analysis of the skeleton. Such approaches have therefore been used to address the particularly significant question of human mobility in antiquity. Successful studies have used stable carbon isotopes in dental and skeletal tissue from prehistoric and colonial period individuals found in Cape Town, or strontium isotopes in similar tissue from prehistoric Beaker period burials in southern Germany.

The use of trace element data, and also strontium isotope data, from archaeological human tissue demands that we are able to discriminate between the in vivo signal and any subsequent post mortem changes. In an attempt to detect such post mortem changes, some studies have concentrated on the mineralogy of excavated bone. In view of the poor crystallinity and large surface area of living bone, it is not surprising that mineralogical changes take place post mortem, which might affect the trace element composition. For example, Sillen has suggested that an increase in the Ca/P stoichiometric ratio of bone mineral to more than 2 may be due to recrystallization of the hydroxyapatite to other calcium phosphates, and the deposition of calcite crystals into the bone. It is not immediately clear what effect these processes will have on the supposed dietary indicator elements, but it is certain that they need to be better understood before convincing archaeological interpretations can be made. In order to address these processes, it has become common to analyze the soil material from the burial context in an attempt to assess the elemental exchange between sediment and bone. This is clearly not of itself adequate and some workers have emphasized the need to consider the availability of exchangeable ions rather than the total soil composition. This requires an understanding of the physics and chemistry of the soil, including factors such as soil pH and temperature, the presence or absence of organic matter, as well as the geochemistry of the species present and the local groundwater movement, as discussed elsewhere in this review.

Many physical and chemical parameters have been measured on archaeological bone to identify diagenetically altered material (C/N ratio, organic content, amino acid profile of collagen, Ca/P ratio, porosity, mechanical strength, histology, density, “crystallinity”). Some progress has been made on the physical nature of the interaction between groundwater and buried bone, but this needs to be augmented by better geochemical modeling, using information derived from laboratory experimentation on both the organic and inorganic components of the system. On the assumption that most archaeological bone is mineralogically altered in some way, a highly significant question is “can this alteration be satisfactorily removed in order to allow trace element or isotopic analysis of the in vivo mineral phase?”. A common approach to this problem (at least in the context of Sr and Sr isotope measurements on fossil and archaeological bone) is a process known as “sequential washing”, which has been demonstrated to give a residual strontium level that is chemically and isotopically plausible for an in vivo signal. This raises a number of questions focusing around the nature of such recrystallization processes (which are presumably driven by Ostwald processes during the burial period), and the differential solubility of various substituted calcium phosphates, which might be susceptible to a series of controlled laboratory experiments.

### 3.2.5 Organic Analysis in Archaeology

Until recently, archaeological chemists have generally paid more attention to the analysis of inorganic artifacts – encompassing both natural (e.g. stone) and synthetic (e.g. ceramics, metals, glass and glazes) materials. These represent the most obviously durable artifacts in the archaeological record. However, in recent years, increasing attention has been directed at biological materials, including natural products such as waxes and resins, accidental survivals such as food residues, and, above all, human remains, including bone, protein, lipids, and DNA. Some of the methodology for this work has been imported not only from chemistry, biochemistry, and molecular biology, but also from organic geochemistry,
which has grown from a discipline interested in elucidating the chemical origins of oil and coal into one which studies the short-term alteration and long-term survival of a very wide range of biomolecules.\(^{100}\)

Another related discipline in this quest for ancient biomolecular information is molecular paleontology. Collectively, these disciplines and archaeology have much to offer each other, particularly in the recovery of genetic information from animals and plants. In terms of specific archaeological interest, the ability to extract DNA has considerable significance. Hitherto, extraction of nuclear acids from bone some 40,000 years old has been claimed.\(^{101}\) Preserved soft tissue and seed remains also yield extractable DNA. Specific DNA sequences can be targeted, amplified using the polymerase chain reaction (PCR), and compared with sequences in other individuals and modern specimens. However, ancient DNA is severely damaged and fragmented. Contamination of aged samples and extracts with modern DNA is a serious problem and whilst the study of DNA in archaeological samples will constitute a major area of future activity in the discipline,\(^{102}\) current research will continue to focus on the authentication of samples of ancient DNA\(^{103}\) and understanding the extent of DNA damage.\(^{104}\)

Preservation of a wider range of biomolecules has been demonstrated in a number of archaeological contexts. In particular, proteins preserved in human bone have been subject to immunological investigation.\(^{105,106}\) The survival of recognizable protein residues on stone tool surfaces\(^{107,108}\) hints at the possibility of characterizing artifact use and identifying utilization of particular animal resources and dietary items, although the specificity of the results obtained remains contentious.\(^{109}\)

Organic residues represent amorphous biological debris in the archaeological record. They differ in one crucial respect from the main body of organic remains which archaeologists have studied for many years in that they lack the macroscopic cellular structure present in seeds, wood, leather, pollen, and so on. Typical organic residues include food deposits surviving in pottery containers used for cooking, storing, and serving solid and liquid organic products, the balms in the wrappings of mummified bodies, and traces of coloring dyes impregnated in ancient textiles. The most effective approach to the identification of organic residues is molecular analysis. Ideally, the presence of a specific compound or distribution of compounds in an unknown sample is matched with its presence in a contemporary natural substance. The use of such molecular markers is not without problems since many compounds are widely distributed in a range of natural materials, and the composition of an ancient residue may have changed significantly during use and burial. In general, molecular markers belong to the compound class defined as lipids, a heterogeneous group of molecules which includes fats and oils and often includes compound classes with common solubilities, such as the constituents of resins and waxes.

Combined gas chromatography/mass spectrometry (GC/MS) has been used widely in the identification of ancient lipid residues contributing to studies of artifact use patterns and food consumption.\(^{110}\) The potential for preservation is relatively high and a wide range of fatty acids, sterols, acylglycerols, and wax esters has been identified in visible surface debris on pottery fragments or as residues absorbed into the permeable ceramic matrix. Isolation of lipids from these matrices is achieved by solvent extraction of powdered samples. Despite their stability relative to other classes of biomolecules, lipids often undergo alteration, with the reactive sites undergoing oxidation (leading to the loss of double bonds) or hydrolysis (cleavage of ester linkages). Lipid degradation combined with other factors, such as the mixing of fats from diverse sources, has made precise identifications problematic. Often it is only possible to conclude that animal or plant lipid, or indeed a mixture of the two, is present. In certain circumstances, organic products consistent with specific sources can be identified due to the presence of long-chain waxy compounds found in epicuticular waxes of plants.\(^{111}\) The recent introduction of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) has shown great promise in differentiating ancient lipid residues (e.g. discriminating ruminant from nonruminant animal fats).\(^{112}\)

Lipids can be used to inform studies of decay sequences and decay products associated with human remains, notably preserved soft tissue from peat-buried bog bodies and soft tissue remains in permafrost. Lipid analysis of the skin tissue from the Tyrolean Ice man has been undertaken. Although many of the ester bonds of the triacylglycerols had been hydrolyzed releasing the fatty acids, some preservation of acyl lipids was evident. However, all triacylglycerols with more than one double bond were completely degraded. Combined histological (showing loss of epidermis) and chemical investigations (revealing transformation of the fat into adipocere) indicated submersion of the body in water for at least several months followed by freeze-drying.\(^{113}\)

Not all the lipids associated with human remains are endogenous. Recent work\(^{114}\) suggests that mycolic acid lipid biomarkers for tuberculosis (TB) (from Mycobacterium tuberculosis) are preserved in archaeological bone from the burial ground (18th–19th century) at Newcastle Infirmary (UK). Mycolic acids are molecules with 60–90 carbon atoms. These acids are mainly esterified to a polysaccharide, which is in turn linked to the cell wall. The authors report the chemical identification of species-specific mycolic acids in 5 out of 21 individuals, which
correlates with the documented frequency of 27.1% TB for the Infirmary. None of the rib samples in the Newcastle study had lesions that might be linked to TB, indicating that TB would not have been diagnosed without the molecular study. The mycolic acids have been “fingerprinted” using high-performance liquid chromatography (HPLC) and this approach is highly complementary to studies based on genetic indicators of ancient disease.

The versatility of lipid molecules as indicators of specific human activities has been demonstrated in the persistence in soils and sediments of biomarkers of fecal material. Remarkably, ratios of certain biomarkers (α- and β-stanols) and the relative presence of other bile acids suggest that it is possible to provide an indication of the animal donor to the archaeological record. The occurrence and persistence of cholesterol in long-buried bone and the ability to determine compound-specific δ13C values is being used as a source of paleodietary information complementary to those obtained on collagen or bone mineral with their longer turnover times. Furthermore the unaltered carbon skeleton of ancient cholesterol ensures that chemical modification has not occurred. Food lipids are by no means the only source of amorphous organic debris. Higher plant resins and their heated derivatives (wood tar and pitch) served as sealants and adhesives, perfumes, caulking materials, and embalming substances. The protective functions of resinous substances in nature reflect their widespread survival in waterlogged contexts. The use of a tar derived from heating birch bark (Betula sp.) has been demonstrated in prehistoric Europe from the early Holocene onwards. This tar served as a ubiquitous hafting adhesive for attaching stone tools to handles of wood, bone, or antler. Birch bark tar is also the source of chewing “gums” excavated from bog sites of Mesolithic date in southern Scandinavia. Recent historical evidence suggests that chewing the tar may have played a role in dental hygiene and in treating throat disorders. Molecules consistent with beeswax (Apis mellifera) have been identified on a pottery vessel dating to the fourth millennium BC in Europe and provide among the earliest evidence in antiquity for the collection of wax and, by assumption, honey. Resins consistent with those of Pistacia sp. have been identified as a part of the bulk cargo of a Late Bronze Age shipwreck. Finally, a find of frankincense from a sixth century AD site in Egypt has been identified by organic analysis.

Although food lipids, plant resins, and wax comprise the largest categories of organic debris identified by GC/MS, there are other striking identifications. Biomarkers identified from plant extracts with psychoactive properties have been reported. By way of example, lactones congruent with the intoxicating drink kava (prepared from the roots of Piper methysticum) have been identified in residues adhering to pottery fragments from Fiji. More systematic investigations have been undertaken on bituminous substances. Bitumen represents the fraction of sedimentary organic matter that is soluble in organic solvents (the insoluble fraction is known as kerogen). The liquid or semisolid varieties of bitumen were widely used in the Near East and Middle East in antiquity, serving as a multipurpose glue and waterproofing material, a building mortar, medicinal agent and as one of the constituents of the organic preparations applied to mummified bodies in Ancient Egypt dating from 1000 BC to 400 AD. Compounds consistent with a bituminous substance include saturated hydrocarbons which have linear (alkylated alkanes) or cyclic (steranes, terpanes) carbon skeletons. These molecules derive largely from microscopic plants deposited in the sediments as well as from bacterial inputs. It has proved possible to identify molecular and isotopic characteristics of the bitumen which enable archaeological finds to be assigned to a particular source of bitumen.

Other methodologies have contributed to identification of residues. In particular, traces of wine have been deduced from chemical “spot tests” for tartaric acid, supported by IR spectroscopy, ultraviolet/visible (UV/VIS) spectroscopy and HPLC. Positive results have been reported with a thin yellowish deposit on a shard from a Neolithic jar (5400–5000 BC) from the site of Hajji Firuz Tepe in the Zagros mountains, Iran. A range of spectroscopic techniques have been useful in archaeological investigations. Although IR spectroscopy can be limited for complex mixtures comprising many degraded components, the technique offers some possibilities for screening organic residues and “fingerprinting” organic substances. In particular, IR spectroscopy has been very successful in characterizing Baltic amber found at prehistoric sites in Europe and distinguishing it from other European fossil resins. A related technique, Raman spectroscopy, has been used to study archaeological materials nondestructively. UV/VIS absorption spectroscopy has been useful in confirming the identity of dyestuffs from the New and Old Worlds. Nuclear magnetic resonance (NMR) has provided valuable information on the structure of highly cross-linked fossil resin samples from around the world. This work builds upon the classic IR spectroscopic program of analysis that began in the 1960s, and identified the source of origin of amber from archaeological sites throughout Europe.

3.3 Special Considerations in the Analysis of Archaeological Material

For the most part, archaeological materials are now analyzed on factory-standard equipment—sometimes on a machine dedicated to archaeological research,
but often on a multiproject instrument. In this sense,
archaological materials are no different from any
other environmental or geological samples which require
analysis. In other ways, however, archaeological material
can pose special problems to the analyst. Restrictions are
often placed on sampling either by physical limitations
or by consideration of aesthetic value. Typically the
resulting samples can be far from ideal from the analytical
point of view – small, fragmentary, and, particularly in the
case of biological samples, often considerably degraded.
They are likely to be contaminated in some way during
burial, and after recovery (postexcavation) may suffer
further contamination due to storage media, handling,
or airborne particles. Samples taken from museum
material which was collected some time ago may have
been subjected to unknown conservation, restoration,
or fumigation procedures. These ubiquitous problems of
degradation and contamination, although not insoluble,
make archaeological chemistry a challenging field, and
usually not one which can be regarded as just another
routine analytical application.

In many ways, there is a close relationship between
forensic chemistry and archaological chemistry. Both
derive evidence from samples obtained from a controlled
recovery situation, and both attempt to reconstruct
patterns of human behavior from material evidence. In
both cases, too, the samples are often unique, and often
far from ideal from an analytical point of view. Attempts
have been made to draw together the two disciplines of
archaeology and forensic science, but an examination
of the analytical literature on both subjects reveals as yet
little evidence of cross-fertilization.

4 SPECTROMETRIC METHODS USING
OPTICAL WAVELENGTHS

Analytical chemistry began to make a sustained impact
on the subject of archaeology following the introduction
of OES as a method of analysis in the 1930s. The
principal interest at the time was understanding the level
of technology represented by finds of ancient metalwork,
especially in terms of alloying, and systematic programs of
analysis were initiated in Britain and Germany leading to
substantial compilations of analytical data. Although
now outmoded as an analytical technique, it provided the
bulk of analyses (in Europe at least) of archaological
metals and pottery until the 1970s, and was particularly
prominent in the large-scale study of the composition
of Greek pottery carried out by the Fitch Laboratory
of the British School at Athens and the Research
Laboratory for Archaeology and the History of Art, Oxford University. Using OES, it was possible to
measure virtually any element present in a 10 mg sample,
in the concentration range from 0.001% to 10%. In
practice, because of the complexity of the emission
spectra, the maximum number of elements measurable
from a single exposure was about 20, with a coefficient of
variation of between 5% and 25% for major and minor
elements.

During the 1970s and 1980s most OES laboratories
switched to atomic absorption spectrometry (AAS), and
this became one of the standard methods for the analysis
of archaeological metals and pottery, with a growing
application to bone in the 1980s. In comparison with OES
or NAA (the principal competitor techniques until the
advent of inductively coupled plasma (ICP) techniques
in the 1980s), AAS had the disadvantage that it required
a liquid sample (causing dissolution problems for silicate
materials), and that it was sequential in operation, thus
limiting the range of elements which could be determined.
Nevertheless, a substantial database of archaeological
analyses has been compiled using AAS, and it has only
been replaced by inductively coupled techniques in
archaeology during the 1990s.

Temperatures up to 10 000 °C are achievable using an
ICP torch in an inductively coupled plasma atomic emis-
sion spectrometer (ICP AES). At these temperatures, all
compounds are completely dissociated and excited, so
that they strongly emit characteristic lines, which are sub-
sequently dispersed and detected using a single detector
system similar to that used in atomic absorption. Although
strictly sequential in operation, the combination of
software-controlled analysis programs and automated
sampling makes the machine quasi-simultaneous. Further
developments have enhanced its performance consider-
ably, such as the use of a mass spectrometer as the
detection system, and the recent development of laser
ablation (LA) systems that allow a solid sample to be
precisely vaporized by a high-power laser, which clearly
has a great deal to offer archaeological analysis.

A major benefit of the ICP torch which has been
exploited over the past few years is that it can be
connected up to a mass spectrometer to give the very
powerful technique of ICPMS. The temperature of the
torch (up to 10 000 °C) is sufficient to ionize approximately
50% of the atoms in the sample, making the plasma an
ideal source of ions which, given the appropriate interface
to deal with the high temperatures involved, can be
extracted from the plasma and injected directly into a
mass spectrometer. Not only is this more sensitive than
the measurement of emission intensities (thus lowering
even further the detection limits for certain elements), but
it also allows the analyst to monitor the concentration of
individual isotopes of a particular element. It also enables
the direct measurement of the ratios of specific isotopes
for a particular element, such as lead.
There have been several comparative reviews of the performances of AAS and the ICP technique, including a recent one by Slavin.\textsuperscript{131} Although ICPAES usually has a limit of detection comparable with flame AAS, it can be seen that an element-by-element comparison often reveals significant differences. In general, the refractory elements (Al, Ti, etc.) are better detected by ICPAES, whereas the heavy (nonrefractory) elements are better detected by flame AAS. For example, with ICPAES Ba has a detection limit of around 0.5 ppb (parts per billion), compared with about 8 ppb by flame AAS, whereas Pb is better detected by AAS (10 ppb compared with about 50 ppb). The use of an electrothermal furnace with AAS generally gives an order of magnitude improvement in limits of detection, and the coupling of a mass spectrometer to an ICP torch gives a further order of magnitude improvement. Equally (if not more) important are the analytical precisions of the various techniques—a measure of the repeatability of the experimental method. In routine applications, the precisions are usually quoted as around 0.5% for flame AAS, 1.5% for ICPAES, 3% for furnace AAS and 2–3% for ICPMS, although individual laboratories may be able to improve substantially on these figures for particular applications. Recently, a review has been published concerning the intercomparability of silicate analyses carried out by ICPAES and AAS for the purposes of comparing data on archaeological ceramics.\textsuperscript{132} It concluded that the results from both methods were sufficiently close that common databanks could be established, providing adequate care had been taken to include certificated standards within each run to monitor performance on the more difficult elements.

LA is potentially extremely attractive for archaeological applications, since it offers the possibility of spatially resolved microanalysis of solid samples, in a manner similar to electron microscopy, but with greater sensitivity and the potential for isotopic analysis. In this technique, a high-energy pulsed laser is directed onto a solid sample, with a beam diameter of less than 25 μm. The pulse vaporizes about 1 μg of material, to leave a crater 50 μm deep. The vaporized sample is swept into the ICP torch via a carrier gas. Current equipment allows solid samples, approximately flat, of 35 mm diameter to be accommodated in the LA unit. The analytical sensitivity in terms of minimum detection limits is poorer for LA than for solution analysis, and the detection limit for a particular element (or isotope) depends on the solid matrix being analyzed. Nevertheless, the potential advantages of such a system far outweigh these problems, and laser ablation inductively coupled plasma mass spectrometry (LA/ICPMS) is likely to become a powerful technique in archaeology, as in all other materials sciences. The potential of the new generation of high-resolution ICPMS instruments using multicollector detection is discussed in section 5.

5 X-RAY AND ELECTRON TECHNIQUES

XRF has been a popular technique for the chemical analysis of archaeological artifacts since the early 1960s, largely because it was perceived as nondestructive providing a reasonably flat and clean part of the object could be presented to the spectrometer. Early instruments for archaeological research used wavelength-dispersive detection, and were soon adapted to use a curved crystal to reduce the spot size of the analyzed area from a circle of ca. 5 mm diameter down to a couple of millimeters (the so-called “Milli-probe”).\textsuperscript{133} The use of energy-dispersive X-ray fluorescence (EDXRF) instruments was pioneered during the 1970s,\textsuperscript{134} largely using home-made mounting equipment so that a large sample could be orientated toward the X-ray tube and detector to give maximum flexibility of sample size. Some machines were designed to use a large vacuum chamber enclosing the sample (in which cases elements down to sodium could be detected, but not with great sensitivity). Others operated in a nonevacuated environment (“air path”), which limited the analyses to elements heavier than potassium in the periodic table, but did allow the majority of ancient metal alloys to be analyzed in a rapid fashion. Yet others experimented for a while with an enclosing bag containing helium, which allowed analysis down to about silicon. Several large analytical programs on materials such as metals (especially coinage), ceramics, porcelain, and glass, obsidian, and even jet were carried out using XRF during the 1980s and later. XRF continues to be a standard tool for major and minor elements in geological whole-rock analysis where the sample can be pelletized or standardized in some way, and this method has been used to some extent for the routine analysis of ceramics and lithic raw materials in archaeology. XRF is still a valued tool in many museum and archaeological laboratories since it can provide an almost instantaneous semiquantitative identification of a wide range of inorganic (and occasionally organic) objects. As a research tool, however, electron microscopy is often the preferred technique, for the following reasons.

One major consideration in the archaeological use of EDXRF on essentially unprepared archaeological samples such as coins and glass has been the problems of surface sensitivity. Although by no means the most surface-sensitive of analytical techniques, EDXRF only gives an analysis of the top fraction of a millimeter of the sample. In the case of metals, where the phenomenon of surface enrichment of the more noble metals (either deliberately during manufacture or naturally as a...
result of interaction with the burial environment has long been known, this can be a critical restriction. Similar problems, due to the selective leaching of the alkali elements, have been noted in glass. Although careful sample preparation can minimize these difficulties and provide good quantitative data, it is usual to regard EDXRF analyses of unprepared archaeological materials as qualitative, or at best semiquantitative. This does not compromise its usefulness in areas such as conservation, where a rapid identification of the material may be all that is required, or in other areas as a preliminary analytical screening technique.

The analytical uses of the electron microscope in archeology were developed at about the same time as the development of wavelength-dispersive X-ray fluorescence (WDXRIF), again using specially developed equipment. More recently, however, standard instrumentation has been used, especially since the introduction of large environmental chambers, which ease the sample size restrictions found with conventional equipment. Electron microscopes can be operated with either a wavelength-dispersive (WD) X-ray detector or an energy-dispersive (ED) detector. More powerful instruments are fitted with both. Comparative studies have been made of the performance of WD and ED detectors in the analysis of silicates and vitreous material. These studies show that the accuracy and precision of both techniques are comparable over the normal concentration ranges found in geological and archaeological material, but ED has considerably poorer limits of detection, typically by one or two orders of magnitude – representative figures for the limit of detection by ED detection are 0.05–0.26 wt% of the element.

The principal advantage conferred by electron beam stimulation is the “steerability” and “focusability” of the primary beam. Not only does this allow analysis of small regions of the sample, but it also allows line scans and area scans to be carried out, giving spatially resolved chemical information from the surface of the sample. Line scans across sections through the object are particularly valuable in the study of the changes caused by corrosion of metal artifacts. Area scans give rise to “elemental maps” of the sample surface. Thus, for example, the distribution of uranium can be displayed across the surface of a section through an archaeological bone. This facility is particularly valuable in archaeology, where the samples tend to be inhomogeneous and corroded.

Transmission electron microscopy (TEM) has had as yet limited application in archeology – an exception is the work of Barber and Freestone, who used TEM to identify the nature of the tiny particles involved in the phenomenon of dichroism in the Roman glass known as the Lycurgus Cup. Small dispersed particles of silver–gold alloy in the glass make this object appear red in transmitted light and green in reflected light, and made it one of then technological marvels of the ancient world.

During the 1980s an alternative approach to the X-ray analyses of inorganic materials was developed, utilizing high-intensity, highly focused beams of protons. These beams can be “tapped off” from a particle accelerator and focused onto a sample outside the accelerator (i.e. not in a chamber under high vacuum). This is valuable for archaeological material, since it again removes the need for sampling. The first generation of proton-induced X-ray emission (PIXE) machines had beam diameters of the order of half a millimeter, but more recent machines have micrometer-diameter beams (μ-PIXE), giving spatial resolution similar to that obtainable by electron microscopy. The major advantage offered by PIXE is that the primary beam of protons does not generate a high X-ray background, giving improved analytical sensitivity. Detection levels in PIXE may be as low as 0.5–5 ppm (parts per million) for a wide range of elements in thin organic specimens such as biological tissue. Limits of detection better than 100 ppm have been reported for elements above calcium in the periodic table in inorganic archaeological material. Analyses of archaeological and historical art samples ranging from ceramics, metals, and paintings to postage stamps have been reviewed by Johansson and Campbell.

One other analytical use of X-rays is in the technique of X-ray diffraction (XRD), used to identify crystalline phases in a range of archaeological objects. It has been used extensively (in conjunction with IR spectroscopy) to monitor changes to the crystallinity of archaeological bone as a monitor of diagenetic processes. It is also used (in conjunction with IR and Raman spectroscopy) to identify the various mineral phases in corrosion products on metal surfaces and to identify the high-temperature phases present in archaeological ceramics as an indication of firing temperatures and techniques.

6 NUCLEAR TECHNIQUES

Until the advent of ICP and PIXE techniques during the 1980s, the standard analytical method for producing multielement analyses with detection limits at the ppm level or better was NAA, and it has consequently been widely applied in all disciplines from geology to medicine. It has been popular because it applies to a wide range of materials, giving analytical sensitivities down to the ppb level for some elements on small solid samples. One review showed that 50% of the trace element data reported in the major geochemical journals between 1990 and 1992 were obtained by NAA. NAA has been used on archaeological material since the inception of
the technique in the 1950s, particularly for coinage and ceramics. It has been particularly prominent in the USA, where very few inorganic analyses of any sort have been published using a technique other than NAA. It is still a major technique in archaeological chemistry but increasing difficulties associated with obtaining irradiation facilities, and increasing competition from ICPMS, are eroding this position.

The procedure in use at the British Museum for ceramic analysis is typical of the methods used on a range of materials. Powdered samples (40–80 mg) removed from the ceramic are sealed into silica tubes and packed into an irradiation canister, which can contain up to 70 samples. The canisters are irradiated at a nuclear reactor, and returned to the laboratory four days after irradiation, for a program of γ counting using a germanium solid-state detector. The British Museum program allows 23 elements to be determined from the same irradiation, making the whole analytical procedure extremely economical in terms of information obtained for the cost and time involved. Detection levels can be as low as 1.5 × 10⁻³ ppb for very sensitive elements in a suitable matrix but more typical figures would be around 10 ppb, up to perhaps 10 ppm, for trace elements in geological or biological material. As with all analytical techniques, there is a variation in the sensitivity and detection levels from element to element, but additionally with NAA there are some elements which cannot be “seen” at all, either because neutron irradiation does not produce suitable radioactive nuclei, or possibly because the spectrum has severe spectral interference. Most important archaeologically here are elements such as lead and silicon, which means that NAA often cannot produce “total analyses” for metals, ceramics, and glasses. Some of these problems can be overcome using variations on NAA, such as prompt gamma NAA, but often other methods have to be used for some elements. Despite this, NAA remains the method of choice for many analytical provenance studies, especially for ceramics.

7 MASS SPECTROMETRY

Mass spectrometry (MS) is becoming increasingly important in archaeology, as in other scientific disciplines, both as a technique in its own right, and also as a sensitive detection system in the so-called “hyphenated techniques” such as ICPMS, GC/MS, etc. It is has been of great importance in archaeology for the determination of heavy stable isotope ratios such as lead, or for light stable isotopes (carbon, nitrogen) as used in dietary reconstruction (see section 3.2.4 for the latter). For the heavy elements, a solid source is needed, and this is the basis of thermal ionization mass spectrometry (TIMS), which has become of prime importance in isotope geochemistry. Modern instrumentation uses highly sophisticated systems, such as triple filaments for increased beam stability, and multiple collector devices to monitor several isotope ratios at the same time, which allows samples as small as 10⁻⁹ g to be measured satisfactorily. Lighter elements (up to sulfur) require a gaseous sample, which is prepared by combustion of the sample off-line and injection directly into the spectrometer. Again, multiple collectors are used for increased stability in isotope ratio monitoring. A significant development in the measurement of carbon and nitrogen stable isotope ratios has been the coupling of an on-line combustion system and gas chromatography (GC) interface onto the mass spectrometer, which allows the direct input of solid samples. Not only does this considerably simplify the sample preparation, but it greatly speeds up the throughput of measurements with little loss of precision. In the past five years, as discussed above, continuous-flow isotope ratio mass spectrometry (CFIRMS) has almost revolutionized the isotopic study of human remains, as well as allowing more rapid analysis of other organic materials such as cellulose in tree rings for the purposes of climatic reconstruction.

MS has played an expanding role as an alternative detection system offering much greater sensitivity (as well as isotopically resolved measurements, if required) in a wide range of analytical applications. ICPMS instrumentation using relatively low-resolution quadrupole detection has been used in environmental applications to measure isotope ratios of heavy elements such as Pb in body fluids, plant material, and dust samples to determine the source of metal contamination. It is generally accepted that quadrupole ICPMS measurements of lead isotope ratios are sufficiently precise to detect differences between sources of pollution, but interlaboratory studies of ICPMS measurements on a range of environmental samples suggest that realistic precisions are 0.3% for $^{206}\text{Pb}/^{207}\text{Pb}$, 0.8% for $^{206}\text{Pb}/^{204}\text{Pb}$ and 1.4% for $^{208}\text{Pb}/^{204}\text{Pb}$, which are roughly an order of magnitude poorer than can be achieved for lead isotope measurements by TIMS. This is, however, changing rapidly, as a new generation of ICPMS machines becomes available, which have an ICP source linked to a double-focusing multiple collector “conventional” mass spectrometer, giving precisions expected to be even better than those achievable by TIMS. The first commercial versions of these machines have recently been commissioned, and are certain to have a tremendous impact in archaeology, as elsewhere, over the next few years.

Another important “hyphenated technique” is GC/MS, achieved by coupling a mass spectrometer to the effluent of a GC set-up, which combines the powerful analytical capability of MS with the high degree of separation.
possible with GC. Combined GC/MS has become the workhorse of organic analysis in archaeology, with more than 100 papers published using GC/MS applications during the 1990s. The majority of these investigations have made use of electron ionization mass spectra, although more sophisticated ionization and spectrometric methods of detection are being applied. Analytical pyrolysis is increasingly being used in conjunction with GC/MS. Pyrolysis is the preferred method for breaking up the insoluble or polymeric fractions of organic residues that are not themselves volatile enough for conventional analysis, and thereby allowing separation and identification of the fragments. Py/GC/MS has been applied successfully to the study of fossil and recent higher plant resins and to the macromolecular debris remaining from the burning of food in archaeological pottery vessels. GC/C/IRMS provides an extremely versatile approach to studying isotopic patterns in individual molecules.

8 CHROMATOGRAPHY AND OTHER ANALYTICAL TECHNIQUES

Both preparative and instrumental methods of chromatography have been widely applied in archaeological analysis. Some methods such as thin-layer chromatography (TLC) can be used to separate and isolate molecular compound classes in complex mixtures. The method is less satisfactory for actual identification purposes. GC was employed as early as 1965 to identify wood tars from Neolithic potsherds. The technique remains useful in screening solvent extracts and offers some value in “fingerprinting” certain substances (such as beeswax). High-temperature GC employing capillary columns enables a wide range of lipid compound classes to be separated. Most often, flame ionization detection (FID) is employed to monitor the column effluent. HPLC is more versatile than GC because the sample components need not be in the vapor phase. HPLC has been used in archaeology for the separation of amino acids and peptides (for the purposes of dating and amino acid racemization studies), the analysis of ancient dyes and even the identification of alkaloids (e.g. caffeine and theobromine) characteristic of cacao preserved in Mayan archaeological ceramics. GC/C/IRMS has been used to characterize and monitor the degradation of materials such as bone, but also materials of conservation interest such as adhesives.

Electron spin resonance (ESR) is probably best known in archaeology as a dating technique, where it provides crucial evidence about human evolution in the time period before radiocarbon dating becomes feasible. It has, however, been used as an analytical tool to provenance lithic raw materials such as marble and jasper. It has also been used to detect and measure the degree of heating of ancient materials such as ceramics, bone, soil and even cereal grains. NMR has been sparingly applied to archaeological material, but solid-state $^13$C-NMR has been used to look at organic materials encountered during conservation. Perhaps inevitably, NMR has also been applied to the study of the degradation of archaeological bone.

9 SUMMARY

Although chemical analysis of archaeological artifacts is recognized as a fundamental component of the inquiry into past human behavior and development, the demand for relevant data has been echoed on many occasions. Scientific analysis should be much more than a descriptive exercise which simply documents the date, morphology, or composition of ancient materials. As DeAtley and Bishop have pointed out, no analytical technique has “built-in interpretative value for archaeological investigations; the links between physical properties of objects and human behavior producing the variations in physical states of artifacts must always be evaluated.” The demand for meaningful scientific data also needs to be viewed against the evolution of the discipline of archaeology. Trigger states that “archaeologists have asked different questions at different periods. Some of these questions have encouraged close relations with the biological and physical sciences, while other equally important ones have discouraged them.” Against this backdrop, the contribution of scientific analysis to the study of the past has come under increasing scrutiny. Although the majority of archaeologists acknowledge the contribution of scientific dating and analytical techniques to increasing the information potential of the past, the central concern prevails that scientific studies sometimes proceed in a context substantially devoid of a specific archaeological problem. It would, however, be equally misleading to suggest that chronological, compositional, or locational data generated by scientific techniques have no role to play in providing foundations for interpretations of past human behavior. Perhaps success in archaeological chemistry is difficult to measure. For
some, it may be the implementation of a robust or elegant scientific methodology; for others it may be the degree of integration within archaeological problems. Ideally, it should display characteristics of both. The promotion of genuine interdisciplinary studies rather than multidisciplinary investigation lies at the heart of all archaeological endeavor.

Gravimetry

M. Widmer*
Ciba-Geigy, Basel, Switzerland

Gravimetry is one of the oldest techniques of quantitative analysis. In gravimetry, the analyte is precipitated as a stoichiometrically defined compound. After collecting and drying, the precipitate is weighed on an analytical balance and the analyte is determined from the mass and the known stoichiometry of the analytes in the precipitated compound. Although many instrumental methods have superseded gravimetry it is a very important method for standardization processes. Since calibration is inherent in the relative molecular masses and the stoichiometry of the chemical reaction, it represents one of the few primary methods.

As a closely related method, electrogravimetry is also considered. In electrogravimetry the analyte is deposited on a metal, for example a platinum electrode, by electrolysis with a controlled current and its mass is evaluated from the weight difference of the electrode before and after electrolysis. Electroseparation of two analytes is feasible by judicious choice of the electrode potential.

1 INTRODUCTION

In gravimetry, an analyte (in most cases ionic) is precipitated in the form of an insoluble compound of defined stoichiometry. After collection and drying, the product is weighed on an analytical balance and, from the mass and known stoichiometry, the original analyte is quantitatively determined.

Gravimetric methods are widely used in standardization processes, although volumetric and instrumental techniques have superseded gravimetric methods in most routine and general analytical investigations. Generally speaking, gravimetric methods are extremely accurate, owing to the fact that it is possible to weigh substances to great accuracy with analytical balances. It is common practice to determine a weight to five digits; however, even the most sensitive volumetric and instrumental techniques are rarely more precise than about 1–0.1%.

The accuracy (trueeness and precision) of a gravimetric method depends on the precipitation technique and also on the properties of the precipitate. If high accuracy is demanded, the following requirements must be met:

- definite and reproducible stoichiometric composition of the precipitate;
- low solubility in the mother liquor and in the wash solvent (the analyzed substance must be quantitatively incorporated into the final precipitate);
- minimal interference from other elements and components of the system;
- low surface area of the precipitate (crystalline) so that adsorption of impurities is minimal;
- properties that enable convenient separation of the solid from the mother liquid and efficient washing with a suitable solvent;
- thermal stability, so that the precipitate may be dried conveniently without changing its composition;
- stability of the dried product (hygroscopic properties of the substance are troublesome).

2 GRAVIMETRIC TECHNIQUES

It is of the utmost importance that the precipitation leads to a product of highest purity that can be filtered. Therefore some skill and experience is required when gravimetric methods are to be applied.

Some of the above-mentioned properties can be influenced by the precipitation technique. Crystalline substances generally have a definite stoichiometric composition, they are easy to separate from the original solution, either by filtration or centrifugation, and they may be efficiently washed with a minimum volume of the rinsing solvent. In addition, crystalline substances are characterized by a relatively small specific surface area. Therefore, the surface activity is relatively small (particularly when compared with amorphous or colloidal precipitates) and the amount of adsorbed or occluded material is minimal.

Crystal habit and size can be controlled to a certain extent by the precipitation technique. Rapid mixing of two concentrated reagent solutions results in the formation of...
undesirable microcrystalline products. If the solubility of a substance is extremely temperature dependent, small crystals are obtained by sudden temperature changes, resulting in a lower solubility. If a hot solution is cooled very slowly, the crystal seeds have an opportunity to grow before new crystallization centers are formed. Supersaturated solutions are subject to sudden crystallization processes that produce a heavily occluded material; mother liquor with all its constituents is occluded in the precipitate. These impurities cannot be removed by washing.

As a general rule, hot solutions should be used to form precipitates with the appropriate features necessary for the filtration. Add the reagents dropwise and choose as small a concentration as possible. Stir during the addition of any reagents so that you achieve a homogeneous distribution of all solutes.

A number of volatile solutes and electrolytes are known. Solutions of such chemicals should not be heated, otherwise substantial losses may occur. For this reason, the heating of a solution containing a volatile acid (H₂S, HCl, etc.) or base (NH₃, etc.) is not recommended. For instance, in the gravimetric determination of hydrochloric acid with silver nitrate, the acid solution should not be heated before the addition of AgNO₃. However, after addition of AgNO₃, a temperature close to the boiling point (80°C) is recommended in order to obtain a precipitate which can be conveniently filtered. Therefore, chloride solutions used in gravimetric determinations should not be heated before the addition of AgNO₃, since the precipitation is carried out in an acidic medium (addition of HNO₃) and therefore contains volatile HCl. Before filtration, the precipitation should have settled to the bottom of the vessel, so that the most of the liquid can be removed by decantation.

In the early days the precipitation was collected on a filter paper, which was then burned completely in a platinum crucible to leave the final product only. Later, special ceramic crucibles were made available as filtering devices. In both applications the washing process is essential for the accuracy of final results. To obtain a dry product, the crucible containing the precipitation is dried in an oven. From the weight difference between the empty crucible and crucible plus precipitate, the weight of the precipitate is determined, and from that the weight of the analyte is calculated.

### 3 Evaluation of gravimetric analyses

The aim of a gravimetric analysis is the determination of the concentration \( w_A \) of an analyte in a given sample using the laws of stoichiometry. The result is expressed in Equation (1) and is based on two precise weighings:

\[
w_A = \frac{m_A}{e} \times 100 = \frac{af}{e} \times 100
\]

where \( w_A \) is the content of the component sought (%), \( m_A \) is the mass of the component sought (mg), \( e \) is the mass of the sample before gravimetric treatment (mg), \( a \) is the mass of the substance weighed after precipitation, drying, etc. (mg), and \( f \) is the stoichiometric factor.

The stoichiometric factor \( f \) is the ratio of the molar masses of component \( A \) and its weighing form as shown in Equation (2):

\[
f = \frac{\text{formula weight of the substance sought (g mol}^{-1})}{\text{formula weight of the substance weighed (g mol}^{-1})}
\]

\[ f \times 100 \text{ is the percentage of the substance sought in the substance weighed.} \]

Table 1 gives some examples of the calculation of stoichiometric factors.

The stoichiometric factor \( f \) should be as small as possible, in order to provide for a high sensitivity of

4 ELECTROGRAVIMETRY

In contrast to voltammetric experiments (see section 3), electrolysis can be performed under conditions where the composition of the solution is altered, owing to the quantitative electrooxidation or electroreduction of solution components. These bulk electrolysis techniques are characterized by a large ratio of working electrode area A to solution volume V and convective diffusion-controlled mass transport conditions. The use of large electrodes permits the flow of relatively high current and makes possible the fast conversion of material into product in electrooxidation or electroreduction. The basic principles governing electrode reactions in bulk electrolysis are the same as discussed in connection with microelectrolysis (voltammetric) techniques.

Bulk electrolysis techniques can be classified according to the quantities measured. In electrogravimetric experiments, the weight of the material deposited at one of the electrodes (the working electrode) in a pure form of known stoichiometry is determined. Electrogravimetry belongs to the group of microdetermination gravimetry using the current as reagent.

Electrogravimetry is among the oldest electroanalytical techniques and has become a useful analytical tool in the analysis of metal ions. It is now used primarily for the electroseparation of metals from complex mixtures.

In coulometric methods, however, the total amount of electricity Q consumed in the electrolysis serves as the basis for the quantitative determination of the amount of analyte present or reagent produced (see section 3).

Both electrogravimetric and coulometric methods are highly accurate (true and precise) analytical methods. The evaluation of the analyte concentration requires no preliminary calibration with standard solutions.

4.1 Principle of Electrolysis with Controlled Current

In the electrolytic process a chemical reaction is driven in the nonspontaneous direction by an external source of electricity, by applying a DC voltage to the cell consisting of two electrodes in contact with the solution. The total voltage applied across the cell is distributed as shown in Equation (3) if \( E_{\text{appl}} < E_{\text{equ}} \):

\[
E_{\text{appl}} = E_a - E_c + iR
\]

(3)

where \( E_a \) is the anode potential, \( E_c \) is the cathode potential, \( i \) is the current, and \( R \) is the resistance.

Each electrode potential is considered as the sum of a reversible potential and the overpotential. The reversible potential depends on the standard potential of the electrochemical half-reaction taking place at the electrode and the activities of the relevant substances in the vicinity of the electrode surface.

Let us consider the overall reversible reaction shown in Equation (4):

\[
O + ne^- \rightarrow R
\]

(4)

where both O and R are soluble.

The rate of the electrode reaction depends on the applied potential, and the concentrations of the substances O and R are expressed by the Nernst equation as shown in Equation (5):

\[
E_{\text{appl}} = E^0 + \frac{RT}{nF} \ln \frac{c_O}{c_R}
\]

(5)

As the electrolysis proceeds, that is, as the metal deposition proceeds, the electrode potential decreases with decrease of the metal cation concentration \( c_O \) in the solution. The degree of completion of the bulk electrolysis process can be predicted from the applied potential and the Nernst equation. Supposing that, in the beginning, the concentration of O is \( c_{O,i} \), \( E^0 \) is the standard electrode potential, \( V_s \) is the volume of solution and \( x \) is the fraction of O reduced to R at the electrode potential \( E \), then the number of moles of O at equilibrium is \( V_s c_{O,i} (1 - x) \), while the number of moles of R at equilibrium is \( V_s c_R x \); and Equation (6) shows:

\[
E_{\text{appl}} = E^0 + \frac{RT}{nF} \ln \frac{V_s c_{O,i} (1 - x)}{V_s c_R x} = E^0 + \frac{RT}{nF} \ln \frac{1 - x}{x}
\]

(6)

For example at 99.99% completeness of reaction of O to R (i.e. \( x = 0.99999 \)) the working electrode potential is given by Equation (7):

\[
E_{\text{appl}} = E^0 + \frac{0.059}{n} \log \frac{0.0001}{0.99999} \approx E^0 + \frac{0.059}{n} \log 10^{-4}
\]

(7)

or 236/n mV more negative than \( E^0 \) at 25°C.
Similarly, Equation (8) shows, for electrogravimetric conditions, when metal ions are deposited, for example, on an inert electrode such as platinum:

\[ \text{O} + n e^- \rightleftharpoons \text{R (solid)} \]  \hspace{1cm} (8)

The Nernst equation yields Equation (9):

\[ E_{\text{appl}} = E^0 + RT \ln[c_i(1-x)] \]  \hspace{1cm} (9)

where \( c_i \) is the initial concentrations of oxidant, and \( x \) is the fraction of the oxidized form reduced at electrode potential \( E \).

Considering the extent of electroreduction, the potential shift due to the given degree of completion of electrolysis can be calculated (Equation 6). From this it follows that an alteration for the electrode potential due to electrolysis must be kept in mind when designing a bulk electrolysis experiment for the selective determination of metals.

Let \( c_A \) and \( c_B \) be the initial concentrations of components A and B, respectively, and \( E_A^0 \) and \( E_B^0 \) the redox potential values of the relevant half-reactions. If \( E_A^0 > E_B^0 \), then the condition for the selective separation at \( x = 0.9999 \) is given in Equations (10) and (11):

\[ E_A^0 + \frac{0.0592 \times 4}{n} E_B^0 + \frac{0.059}{n} \log c_B \]  \hspace{1cm} (10)

\[ \Delta E = \frac{0.059}{n}(4 + \log c_B) \]  \hspace{1cm} (11)

In the foregoing it was assumed that the electrochemical reduction of both metal cations is reversible.

For the case shown, the extent of the electrode reaction will be governed by equilibrium conditions, but the rate of electrolysis will be small at potentials predicted by the Nernst equation. The rate of electrolysis is naturally increased with increase of the electrode potential applied, and reaches a limit due to the given degree of completion of electrolysis. Thus, the only practical way of keeping the electrode potential at a preselected value is to measure the cathode potential continuously with respect to a reference electrode. The cell potential can then be adjusted within the desired range. This type of analysis technique is called controlled cathode potential electrolysis or controlled anode potential electrolysis.

The working electrode potential with respect to a third reference electrode is controlled automatically with a potentiostat.

### 4.1.1 Current Efficiency

The current efficiency for an electrode reaction (ith reaction) is equal to the fraction of total current rendered for the ith reaction as shown in Equation (12):

\[ \text{current efficiency for the ith reaction} = \frac{i_i}{i_{\text{total}}} \]  \hspace{1cm} (12)

where \( i_{\text{total}} \) is the total current passing through the electrolysis cell.

A current efficiency of 100% means that no side reaction takes place at an electrode, that is, there is only one working electrode process.

It is beneficial for bulk electrolysis to be carried out with high current efficiency in order to reduce analysis time. In electrogravimetric experiments, 100% current efficiency is not required unless the side reactions produce insoluble reaction products. However, for coulometric titrations, 100% current efficiency is a prerequisite.

### 4.1.2 Electrolysis Cells

Electrode designs used for controlled potential bulk electrolysis experiments are shown in Figure 1. As a cathode, Pt gauze or foil cylinders of diameter 2–3 cm are
commonly used. Platinum electrodes have the advantage of being relatively nonreactive, and can be used for the deposition of a number of different metal ions. However, a protective coating is required before the electrolysis of certain metal ions, notably tin and zinc, to avoid alloy formation.

Amalgam-forming metals can be deposited on Hg cathodes. This procedure is especially used for removing easily reducible elements as a preliminary to the analysis.

The anode can also be made of Pt. Proper positioning of the auxiliary electrode is essential in order to provide uniform current density across the working electrode surface. The location of the reference electrode is also important for the long-term stability of the reference electrode and the $iR$ drop.

The working and the auxiliary electrodes are often placed in separate compartments in order to avoid mixing of the electrolytes. The two compartments are usually separated by a sintered glass disk or an ion-exchange membrane of relatively low resistance that does not contribute appreciably to the overall cell resistance. The use of separators can be avoided by the judicious choice of the auxiliary reaction, in which solid products such as AgCl or inert gaseous products (e.g. N$_2$) are formed.

The cell resistance and the proper positioning of the reference electrode in the cell are important when the electrolysis is carried out in nonaqueous solvents with lower dielectric constant (e.g. acetonitrile, dimethylformamide, ammonia).

4.2 Electrogravimetric Methods

Electrogravimetric determinations require adherent, smooth deposits. The quality of the deposit depends, among other things, on the form of the metal ion in the solution. In general, depositions from solutions of complexed ions are smoother and more adherent than those obtained from solution containing the aquo form of the ion.

The time required for electrogravimetric analysis depends on the current density. However, too high current values may result in deposits of poorer quality. Hydrogen formation during deposition also results in a rougher deposit.

The sensitivity of an electrogravimetric method is limited by the difficulty in determining the small difference in weight between the electrode and electrode plus deposit. In general, the deposit of 0.2–5 mmol material is especially advantageous. Electrogravimetric determinations have been supplemented by coulometric methods, except if the 100% current efficiency requirement cannot be fulfilled.

4.3 Electroseparation

In the previous section, the conditions for selective quantitative deposition of one metal $M_1$ on a solid electrode were discussed. The selectivity in this case means that no appreciable deposition of the other metal $M_2$ occurs under the experimental conditions selected. Thus, for complete deposition of $M_1$ ($\leq 99.9\%$) as Hg amalgam, the electrode potential $E$ must be selected as shown in Equation (13):

$$E \leq E_1^0 - \frac{0.18}{n_1} \text{V at } 25^\circ \text{C}$$

where $E_1^0$ is the standard potential and $n_1$ is the number of electrons taking part in the electrode reaction, whereas for 0.1% deposition of $M_2$, Equation (14) shows:

$$E \leq E_2^0 - \frac{0.18}{n_2} \text{V at } 25^\circ \text{C}$$

Thus, for 99.9% separation of $M_1$, Equation (15) shows:

$$\Delta E = E_1^0 - E_2^0 = 0.18(n_1 + n_2)$$

that is, for ions of valency one, it is 0.36 V.

For electroseparation the Hg pool cathode is the most frequently used.

Electroanalytical Methods (Volume 11)
Electroanalytical Methods: Introduction

FURTHER READING

Introduction

The Karl Fischer (KF) titration is a method of determining the water content of solid, liquid, and gaseous samples. It is the technique preferred for use in industrial quality control. In principle, it involves the oxidation of sulfur dioxide by iodine, in the presence of water, in a buffered solution. An alcohol is used as the preferred solvent. The water is converted stoichiometrically and therefore its quantity is determined indirectly. The end-point (EP) is reached when there is an excess of iodine. It can be indicated visually, photometrically or electrochemically. According to state-of-the-art technology, a double platinum electrode determines a voltammetric indication. The KF titration can be carried out either volumetrically or by coulometry. For a volumetric titration, the iodine is added by volume to the titration cell containing the sample. In a coulometric titration, iodide is oxidized at a platinum electrode and the iodine formed reacts with the water. The amount of current necessary in the generation of the iodine is directly related to the quantity of iodine generated, according to Faraday's first law. In practice, special titrators for the KF titration are available. Preformulated reagents are similarly available ready for use. Water in an extensive number of materials can be determined by KF titration. Chemicals, pharmaceuticals, oils, plastics and foodstuffs are examples of typical sample types. The measurement range spans a few ppm to 100% water. The KF titration is described in ISO 760 and as part of many other international standard procedures. Other methods for the determination of water content include loss-on-drying, IR spectroscopy or azeotropic distillation.

1 INTRODUCTION

The water content of various products is an important quality consideration in industrial processes, and, for a raw material, is often taken as a correction factor in the measure of its worth. For example, for oils and cereals, the proportion of water in the gross weight of a delivery is taken into consideration in the price. For intermediate products, such as plastic granulates or tablet powders, the water content influences the mechanical characteristics, e.g. the flow capability in a press. In the final product of a foodstuff, the water content must sometimes be determined by law and can also influence the storage stability. For these reasons an exact determination of the water component of the material is necessary.

It is necessary to distinguish between moisture and water determination. To be exact, moisture is referred to...
as bound water. It can also be used to describe a bound solvent or an evaporated substance. In general, moisture is determined by using an oven. Water, on the other hand, is determined chemically by the KF titration. Both surface water and water bound in crystals can be determined in this way.

Water determination according to the KF method is an analytical technique for determining the water content in various matrixes. Chemically, it involves the oxidation of sulfur dioxide by iodine, with the consumption of water, in a buffered solution. Organic solvents are used as the solvent for the sample as well as for the working medium in the titration cell. Methanol, ethanol and higher propylene glycol mixtures are most often used. The KF titration can be carried out both volumetrically and coulometrically.

The volumetric titration is carried out with a one- or two-component reagent. When a one-component reagent is used, the buret of the titrator contains all the necessary reagents dissolved in an inert solvent. Methanol or a mixture of alcohols serves as the working medium in the titration cell. This is then pretitrated by the KF reagent in order to remove any traces of water from the cell and working medium. Then the sample is added and its water content determined automatically.

In a two-component reagent the reactive components are separated. The so-called “titrant” contains a preset amount of iodine in a solvent, which can be either methanol or ethanol. The buret of the titrator is then filled with this solution. A base and sulfur dioxide are dissolved in the “KF solvent”, which is added to the titration cell and pretitrated to dryness. The sample is then added and its water content determined.

The one-component reagent has the advantage that it can be used with a wide variety of different working media. The two-component reagent is distinguished by its faster titration rate and greater polarity. Typical water contents for volumetric KF determinations are between 0.5 and 50 mg water. Figure 1 shows a typical KF titration curve of time vs reagent added.

A different composition is used for KF coulometry. The reagents contain a solution of iodide rather than iodine, which is then generated from the iodide at a platinum electrode. The iodine then reacts with sulfur dioxide according to the KF chemistry, with the loss of water. The current necessary to generate the iodine is measured. The amount of iodine is determined using Faraday’s law and the water content consequently calculated. To carry out a coulometric determination the reagents are added to the titration cell. These solutions must first be pretitrated as in the volumetric method. Any water in the titration cell or dissolved by the reagent from the air is thereby removed. Since coulometry is more sensitive, this pretitrination process takes longer than a volumetric titration. The sample is injected, via a septum, into the reagent. Modern titrators calculate the amount of water automatically after injection of the sample. Typical absolute values of water analyzed by coulometry are between 50 and 2000 µg.

2 HISTORY

In 1935 the German chemist Karl Fischer was required to determine the water content of liquid sulfur dioxide. Neither loss-on-drying nor distillation were suitable for liquid samples, and he had to find an alternative method. During his investigations he stumbled across the Bunsen reaction, Equation (1), which describes the iodometric determination of sulfate in a buffered, aqueous solution.

\[
\text{SO}_2 + I_2 + 2H_2O \leftrightarrow H_2SO_4 + 2HI \quad (1)
\]

According to Equation (1), a determination of the water content should also be possible if the sulfur dioxide is present in excess and the protons that are consequently produced are taken up by a base. Fischer put together his reagent using sulfur dioxide, iodine and pyridine, with methanol as solvent. He formulated Equation (2).\(^{1}\)

\[
\text{SO}_2 + I_2 + 2H_2O + \text{Py} \leftrightarrow H_2SO_4 + 2HI \text{Py} \quad (2)
\]

where Py represents pyridine. The EP was indicated by the color change from yellow to brown. Using this one-component reagent, he carried out the first volumetric KF titrations and determined the water content of sulfur dioxide and various different solvents.
In 1939 the reaction mechanism was re-examined by an American research group. Smith et al. formulated the two-step reaction, Equation (3), with a different molar relationship of water to iodine of 1:1,

$$\text{H}_2\text{O} + \text{SO}_2\text{-}^*\text{Py} + \text{Py}^*\text{I}_2$$

$$+ \text{Py} + \text{MeOH} \leftrightarrow 2\text{HI}^*\text{Py} + \text{Py}^*\text{SO}_3 \quad (3a)$$

$$\text{Py}^*\text{SO}_3 + \text{MeOH} \leftrightarrow \text{Py}^*\text{MeSO}_3\text{H} \quad (3b)$$

where MeOH represents methanol. By 1943 Wernimont and Hopkinson had introduced the electrochemical dead-stop EP detection for the KF titration.

During the years that followed, there were further improvements in KF reagents, but the next big step came in 1959 when Meyer and Boyd published the coulometric KF titration. Further investigations were published in the 1970s concerning the kinetics of the reaction. In 1974 Cedergren discovered that the reaction rate is dependent on the concentration of iodine, sulfur dioxide and water. Verhoef and Barendrecht found that pyridine functioned only as a base and was not part of the reaction itself. From these observations Scholz formulated Equation (4), the version of the reaction equation that has been accepted since 1984,

$$\text{SO}_2 + \text{HO-} + \text{B} \leftrightarrow \text{R-SO}_3^- + \text{BH}^+ \quad (4a)$$

$$\text{R-SO}_3^- + \text{I}_2 + \text{H}_2\text{O} + 2\text{B} \leftrightarrow \text{R-SO}_4^{2-} + 2\text{I}^- + 2\text{BH}^+ \quad (4b)$$

where B is a base. An alkyl sulfite is formed within the reagent: from the alcohol used as solvent and the sulfur dioxide (Equation 4a). Wuensch and Seubert isolated this reagent: from the alcohol used as solvent and the sulfur dioxide (Equation 4a). Wuensch and Seubert isolated this reagent: from the alcohol used as solvent and the sulfur dioxide (Equation 4a).

**3 DEFINITIONS**

One-component reagent. A volumetric reagent containing sulfur dioxide, base and iodine in an organic solvent. It is used with working media such as alcohols, or mixtures of organic solvents and alcohols.

Two-component reagent. A volumetric reagent consisting of a titrant and solvent. The solutions are not mixed prior to use but are used separately, in contrast to the former pyridine-containing KF reagents.

Titrant. An alcoholic iodine solution.

Solvent. The solution containing the base and sulfur dioxide and which is added to the titration cell.

Anodic reagent = anolyte. A reagent consisting of iodide, a base and sulfur dioxide in an alcohol. It is the reagent in which the coulometric KF reaction takes place.

Cathodic reagent = catholyte. A reagent consisting of organic salts in an alcohol. It is the reagent in which the coulometric cathode reaction takes place, i.e. the reduction reaction. It counteracts the iodide oxidation and normally involves the reduction of protons to hydrogen.

Titer. The water equivalent of the measurement reagent given in mg water per ml reagent.

Drift. The blank value in the titration cell prior to the addition of water. Drift is caused by moisture ingress into the cell and by side-reactions which consume iodine. Modern titrators determine and display the drift automatically. The drift is given in different units depending on the instrument supplier: $\mu$g min$^{-1}$, mg min$^{-1}$, $\mu$L min$^{-1}$ or $\mu$g s$^{-1}$ are in use.
4 INSTRUMENTATION

Due to the special qualities of the water content determination by KF titration it is perhaps understandable that specific analytical instruments for this titration have been on offer for many years. As a result of the enormous developments in the field of microprocessor technology, many of these analytical instruments are now driven by microprocessors. In practice, there are two different instruments accepted for the KF water determination: the volumetric KF titrator and the coulometric KF titrator. Both techniques use the EP titration method, and the titration stand consisting of the titration cell and stirrer plays a particularly critical role.

4.1 The Titration Stand
The atmospheric moisture present in every laboratory is a common source of error in KF titration. This moisture can penetrate the sample, titration reagent and titration cell, and thereby cause incorrect results. Modern analytical instruments for the KF water determination (such as that in Figure 3) reduce the influence of atmospheric moisture as far as possible by ensuring that the following measures are incorporated into the titration stand.

The stand is particularly airtight and has special input ports for the addition of solid, liquid or gas samples. In order to minimize the ingress of atmospheric moisture when changing the reagents, a pump is often integrated into the stand. This pump can suck out used reagent and pump in fresh without having to open the titration cell. During the pumping, it is impossible to avoid air being sucked into the titration cell. Moisture ingress in this way is normally avoided by passing the air over a molecular sieve. No titration stand is absolutely closed to the atmosphere and very small quantities of water can always seep in. Modern KF titrators continually condition the titration cell and determine the quantity of water that has seeped into the cell over a particular period of time. This value is displayed as drift, e.g. as µg H₂O or µL of titration reagent required per minute. The drift is continually on display and the user therefore has a constant measure of the condition of the titration stand. The drift value is also measured at the beginning of the titration and it can therefore be taken into consideration in the final result.

As with all EP titrations, good mixing of the reagents is an important prerequisite for a fast and exact KF titration. Therefore a magnetic stirrer is built into the titration stand of a modern analytical instrument for KF water determination.

4.2 Volumetric Karl Fischer Titration
KF titrators of today are, without exception, fully automatic. The water determination is carried out independently by the press of a button, with the water content calculated and displayed or printed out, according to good laboratory practice (GLP), on an attached printer. To ensure that an automatic titration is possible the volumetric KF titrator has the following essential components.

4.2.1 Motorized Volumetric Buret with a Titration Stand
This buret enables a precise dosing of the titration reagent. To ensure that the hub can accurately add reagent in the microliter range, it is set up with 10,000 steps.

4.2.2 Exchange Unit
The exchange unit was developed to dose the titration reagent. It consists of a cylinder, buret, tap, buret tip and the stock bottle containing the titration reagent. In order to protect the reagent from ingress of atmospheric moisture, the stock bottle is fitted with a drying tube.

4.2.3 Indication System
Normally a bi-voltammetric indication is used as the indication system for the EP of a volumetric KF titration. For this a double platinum electrode with a constant current (e.g. 50 µA) is used. Whilst iodine is reacting with water in the titration cell, there is no free iodine in the titration solution. A high voltage is necessary to maintain the preset polarization current of the electrode. As soon as all the iodine has reacted with the water, free iodine will remain in the titration solution. This free iodine considerably reduces the voltage, which is necessary to maintain the preset polarization current.
4.2.4 Controls for the End-point Titration

In a KF titration the titration reagent must be added as fast as possible from the buret and exchange unit, and the addition should be stopped exactly at the EP. The control of modern KF titrators adapts itself to the course of the titration curve and thus leads to short titration times and very accurate results.

4.2.5 Integrated Communications

A display and keypad are available to the user in order to input control parameters, sample data for the calculation and the documentation and to be able to read the results. Top-of-the-range KF titrators display a live titration curve in the display, which can give the user useful information about the course of the titration.

4.2.6 Method of Storage

A storage capability is necessary to save preset KF titration methods. In each laboratory at least two methods are necessary: the titer determination and the water content determination. If various different samples are to be analyzed the optimum titration conditions can be saved for each different sample type. Then all that has to be done is to call up the right sample, add the sample and start the determination.

4.2.7 Interfaces

Interfaces for a balance and data system (laboratory information management system (LIMS)) enable the KF titrator to be integrated into the modern analytical laboratory.

4.3 Coulometric Karl Fischer Titration

Coulometric KF titrators are also exclusively automatic. The water determination is carried out independently at the press of a button, with the water content calculated and displayed and documented on a printer connected to the titrator. They are differentiated from volumetric titrators by the following aspects. Instead of the motorized buret to dose the iodine solution, coulometers have a generator current circuit such that iodine can be generated electrochemically. For the iodine production there is a generator in the cell rather than the buret tip. In practice there are two types of generator electrode: those with and those without a diaphragm. Wherever possible a generator without a diaphragm is preferred because handling is then easier.

Owing to the smaller amounts of water being determined, a more sensitive indication set-up is preferred. The indication principle is, in effect, identical to that in the volumetric KF titration, only here an alternating current is used for the polarization of the double platinum electrode. Coulometric KF titration is a micro method and particularly suitable for the determination of small quantities of water. Owing to the high sensitivity, particular consideration has to be paid to contamination by moisture from external sources.

The water content of a wide range of samples, from diverse industrial processes, can be determined by using the KF technique. For this reason, special instruments are available for the preparation of samples that are analyzed regularly. Additionally, automated instruments are available.

4.4 Thermostatic Titration Cells

Substances which dissolve slowly in methanol or the KF working medium, cause drifting EPs. The same is true for solids, for example foodstuffs, which give up their water only very slowly. In such cases, titration at 50–60 °C can accelerate the dissolution of the sample or the release of its water. Slow side-reactions sometimes involve iodine and therefore a stable EP is impossible to achieve. It can then be advantageous to carry out the titration at low temperatures, which can reduce the effect of the side-reaction.

Special titration cells are available for these techniques. They are constructed with an outer glass jacket through which a liquid can be pumped. When attached to a thermostat or cryostat the titration temperature can be adjusted.

4.5 Karl Fischer Oven

Many substances only release their water at high temperatures and are therefore unsuitable for the KF titration. These samples can be heated in an oven to between 100 and 300 °C and their water evaporated. The evaporated water is then carried over into the titration cell via a heated, inert stream of gas and titrated either coulometrically or volumetrically. The KF oven can be used for insoluble solids (e.g. plastics and salts), where the water can be released at temperatures above 60 °C fairly rapidly, and also for solids and liquids that react with the KF titration reagents (e.g. ascorbic acid, mineral oil).

4.6 Automation of the Volumetric Karl Fischer Titration

The aim of many laboratories is to increase the throughput of samples and so improve business efficiency and relieve the personnel of routine work. For this reason, sample exchangers were developed. Samples are weighed into sample beakers, which are then closed with aluminum foil in order to protect them from the ingress of atmospheric moisture. When they are at the titration position they are
A typical, automated sample processor. A defined volume of solvent is added. Then the desired dissolving time or extraction time elapses before the KF titration is started. Using such equipment, large numbers of samples can be processed fully automatically. Sample exchangers will also work overnight or during the weekend.

4.7 Oven Sample Processor

Water determination in plastics, oils, emulsions or salts often cause problems. They can cause contamination of the oven and titration cell, side-reactions, reduced lifetime of the reagent, long analysis times and high cost due to the fact that the possibility of automation is limited. An oven sample processor (Figure 4) has been developed to avoid direct contact between the sample and titration cell and thereby avoid the above-mentioned problems. In addition, the full capacity of the reagent is utilized to the optimum. Both the KF volumetric and coulometric titrator can be set up in coordination with the oven sample processor. The samples are weighed in the small (glass) sample boat, which is then sealed with a septum and placed on the exchanger. When the small sample boat reaches the workstation, the oven sample processor is lowered and the septum is pierced with a needle. At the same time the sample boat is pushed into the aluminum heating block and the heater is switched on. The needle has two openings: an inert gas enters the sample boat via the first one, and leaves through the second. The inert gas then passes into the titration cell along with the evaporated water of the sample. The water is then titrated.

5 REAGENTS

The reagent Karl Fischer described has a number of disadvantages. Apart from the strong smell of pyridine, it displays a very fast fall in the titer value. One-component KF reagents are generally unstable. A slow-side reaction, which involves iodine, takes place within the reagent, and so diminishes the titer. Pyridine-containing reagents often decompose completely within a very few weeks but a modern pyridine-free reagent has a titer decrease of less than 10% per year if stored correctly. Additionally, the ingress of atmospheric water into the reagent can cause the titer value to decrease. Air humidity has a great influence on the stability. A liter of air contains up to 15 mg water and therefore it must be dried before being pumped into the titration cell or bottle of reagent.

5.1 One-component Reagent

A pyridine-containing one-component reagent has been described. The titer of these reagents is not given, but must be determined daily since it drops rapidly. Commercially available, pyridine-free reagents are offered with various different concentrations. The water equivalence is often contained in the name of the reagent. Reagents of titer 5, 2 and 1 are the norm. They are used in conjunction with methanol or other special working media. The working media can be varied in order to improve the solubility of the sample or to minimize side-reactions. A chloroform/methanol mixture would be used, for example, to aid the solubility of fats. An ethanolic medium will reduce a side-reaction of the sample with methanol.

Aldehydes and ketones react with the components of a usual KF reagent, and therefore special reagents are available for such samples. They have a K in the name, referring to ketone. The water determination is carried out with a one-component reagent of titer 5 in a special, methanol-free working medium. The main components of this working medium are chlorinated or methoxylated alcohols.

5.2 Two-component Reagents

Two-component reagents consist of a titrant and a KF solvent. The titrant is available with a titer of 5 or 2. For general use both methanol- and ethanol-based KF solvents are used. Solvents such as chloroform or formamide can be added to the KF solvent to aid sample solubility. There are also special products for nonpolar samples available.

5.2.1 Coulometric Reagents

Reagents for coulometry are in the form of an anolyte and catholyte. The KF reaction takes place in the anode reagent. This contains sulfur dioxide, an organic base and a soluble iodide in an alcoholic solvent. Anode reagents
have an A in the name. For general purposes an anolyte that does not contain a chlorinated hydrocarbon is used. For oils, a chloroform-containing anolyte is used; for ketones, a methanol-free anolyte. The reduction takes place in the associated catholyte. The sample does not come into direct contact with the catholyte, and therefore an alcoholic catholyte usually based on methanol can be used for almost all applications. The methanol-free reagent is necessary only for a ketonic sample. Catholytes can be recognized from the C in their name.

5.3 Auxiliary Products

In addition to the actual KF reagents, a whole array of auxiliary products is available. Buffers and acids allow the setting of an optimal pH. Karl Fischer standards with a predetermined water content are used to carry out a titer determination and to check the functioning of the instrumentation.

6 STANDARDIZATION, CALCULATION AND CONTROL OF THE RESULTS

6.1 Titer Determination

Although a titer is given for volumetric reagents, this must be checked at regular intervals. The titer of a one-component reagent falls due to a side-reaction and there is always the possibility of ingress of moisture from the atmosphere, which also reduces its value. Since the titer is actually a measurement of volume, there is also a temperature dependency.

The titer can be determined using pure water, salts with a constant water content and liquid water standards. Pure water is injected into the cell using a microliter syringe. The titer is calculated according to Equation (5):

$$\text{titer} = \text{water equivalent} = \frac{\text{amount of water}}{\text{volume of reagent}}$$

where the amount of water is in mg, and the volume of reagent is in mL. Sodium tartrate-2-hydrate is used as the solid standard. This salt is not hygroscopic, it dissolves in methanol and has a constant water content of 15.66%. The titer is calculated according to Equation (6):

$$\text{titer} = \text{water equivalent} = \frac{\text{sample size} \times 0.1566}{\text{volume of reagent}}$$

where the sample size is in mg, and the volume of reagent is in mL. Liquid water standards consist of a non-hygroscopic solvent mixture that contains 0.01–1% water. The standard (1–2 g) is weighed into the cell by difference. The calculation for the 1% standard would be as in Equation (7):

$$\text{titer} = \frac{\text{water equivalent}}{\text{volume of reagent}} = \frac{\text{sample size} \times 0.01}{\text{volume of reagent}}$$

where the sample size is in mg, and the volume of reagent is in mL.

The titer determination is not only an exact measure of the water equivalent but is also a control of the working conditions. If the titer falls dramatically, this can indicate moisture in the reagent. If the values vary considerably from one another the titration cell may not be firmly closed.

A titer determination or any other calibration procedure is unnecessary in the case of coulometry. It is an absolute method in which the amount of iodine is calculated by using Faraday's constant.

6.2 Sample Size and Calculation of the Water Content

Sample size depends on the method, water content of the sample and the desired accuracy. Table 1 gives some idea of appropriate sample sizes.

6.3 Control of the Result

When validating the KF titration, various sources of error need to be considered. The result can be incorrect due to an error in the titer value, or a deficient reagent or instrument. Additional errors due to a reaction between the sample and reagent are also possible. The whole titration system, i.e. the instrumentation together with the reagents, can be checked using a certified water standard. The water content of the standard is determined during its manufacture by obtaining numerous results at various sample weights. In order to guarantee the KF system, the result obtained with the standard must lie within a predetermined standard deviation limit. Table 2 shows a typical overview of results.

This procedure checks both the KF apparatus and reagents together. If the results do not fall within the accepted limits of error then the source of the error must

7 SAMPLE PREPARATION

Due to the wide area of application for the KF titration, there are countless different samples where the water content needs to be determined. It is only possible here to cover the sample preparation and methods for the various different classes of substance rather than individual materials.

7.1 Solids

Solids usually have water bound in two different states. It can be adsorbed on the surface of the solid or be in the form of crystallized water or trapped water in the solid. In order to determine the whole water content it is preferable that the sample is fully dissolved. Since many materials do not dissolve in methanol, additional solvents are often added to aid solubility. For lipophilic substances, e.g. fats, a working medium is used which consists of 50% methanol or KF solvent and the remainder is chloroform or a suitable alcohol. To dissolve polar substances the working medium is made up of 50% formamide.

For better solubility it is always recommended to reduce the size of large pieces. The sample can be crushed using a pestle and mortar, ground in a laboratory mill, or cut into small pieces. If there is no working medium that dissolves the sample, an extraction titration is sometimes also possible. The sample is ground as fine as possible and suspended in the working medium. The water is then titrated. The hygroscopic solvent extracts the water from the solid. After the EP has been reached it is recommended that a subsequent standard addition is carried out, as described in section 6.4, to ensure that the water is completely extracted. To improve the distribution of the sample, a high-speed stirrer or homogenizer (Ultra-Turrax®, IKA Werke, Staufen, Germany) can be installed inside the titration cell. The sample is dispersed during the titration, which optimizes the conditions for such samples.

A further possibility for determining the water content of insoluble samples is external extraction. Here, a known amount of a hygroscopic solvent, typically dried methanol, is added to the sample in a volumetric flask. After a period of stirring, an aliquot is taken and the
water content titrated. The result must take into account the blank value of the methanol. When small quantities of water are analyzed, not only the blank value of the solvent but also a blank of the procedure should be determined. For this an identical volumetric flask is taken, filled with the same volume of methanol, stirred under the same conditions for the same length of time and an aliquot taken and titrated to the same volume. Already titrated KF solvent can also be used to extract water from samples. Pretitrated anolyte from coulometry is best suited here due to the very small amounts of water involved. A syringe is rinsed numerous times with the pretitrated anolyte until the syringe is completely free of water. A distinct volume of water-free anolyte is then used as extracting solvent. In this case the blank is always zero.

7.2 Liquids

Liquids are ideal samples for the KF titration. They are injected into the titration cell, via a septum, by using a syringe. The cell remains in an ideal water-free condition because ingress of atmospheric water from outside can be minimized. The coulometric cell should, in general, never be opened for sample addition. Therefore, a sample in a liquid or gaseous state is a prerequisite for the KF titration by coulometry. The mass of sample titrated is measured by weighing by difference. Dosing by volume is generally less exact than by weight.

Liquids can also present a solubility problem or, put another way, a problem with mixing, if the sample and working medium have very different polarities. In principle, a titration in two phases is possible with sufficient stirring, but, where possible, only one phase should be present. To improve the solubility of fats, oils and other nonpolar samples, chloroform, propanol or other higher alcohols, e.g. hexanol, can be used. Polar samples can be dissolved if formamide is added.

7.3 Gases

The water content of gases can also be determined by the KF titration. The gas is directed into the titration cell. The water content of the gas is then transferred to the KF reagent. Sometimes the gas dissolves in the reagent and sometimes it bubbles out. If the bubbles are not too large this does not affect the KF titration. In practice, a fine stream of bubbles is achieved by using a sieve-type tip to the insert tube and therefore good dispersion of the gas. Gases normally contain very small amounts of water and therefore coulometry is the preferred method of analysis. Volumetric titration can also be carried out, although a reagent with a low titer must be used. The amount of gas passed through the titration cell is measured in volume and the water content result obtained is consequently in mg L$^{-1}$. It must be noted that the water content of gases is not always distributed homogeneously. If the gas is adsorbed on the inside of the gas cylinder, higher values are obtained at the start of the determination than when equilibrium has been reached. In order to ensure that there is a homogeneous distribution of water in the gas, a constant flow of the gas should be allowed to bubble through the titration cell for an hour and the drift observed. A titration should only then be carried out when the drift has reached a stable value.

7.4 Oven Method

For the water content of samples that react with the KF reagents or that are completely insoluble, the oven method is recommended. This method is described in section 4.5.

8 IMPORTANT APPLICATIONS

The KF reaction is a redox reaction that takes place in an organic solvent. Oxidizing and reducing agents affect the reaction just like substances that react with the working medium. Other interferences take place when a sample is not fully dissolved. Here the water is only released slowly and the titration displays a drifting EP. In order to ensure that the sample fully dissolves, different solvents or physical techniques can be used. The following section gives an overview of the most frequently titrated sample types. A more complete coverage of sample applications is given in the HYDRANAL Guide.$^{(16)}$

8.1 Chemicals

8.1.1 Inorganic Compounds

Inorganic salts rarely dissolve in methanol. In order to guarantee the determination of the entire water content, the salt must first be fully dissolved. A mixture of 50% formamide and 50% methanol dissolves some alkali and alkali earth salts. Prior grinding of the sample and warming of the titration cell accelerates solubility. Most inorganic salts do not dissolve in organic solvents. The oven method is then used. The water is evaporated from the sample, carried into the titration cell via an inert gas, and titrated according to the KF method. Many oxides and carbonates react with the KF reagent and a direct titration is not possible.

Inorganic salts and bases can also be titrated by KF titration, in principle, although the pH in the titration cell must be considered. The reaction proceeds too slowly if the environment is too acid, and the titrator consequently finds no EP. In an alkaline environment there is a side-reaction that consumes iodine and therefore causes a high
result or a vanishing EP. When titrating acids, a suitable buffer, e.g. one based on imidazole and sulfur dioxide, is recommended and, for basic samples, salicylic or benzoic acid is added to the working medium.

8.1.2 Organic Compounds

Organic compounds are very diverse and often characterized by many different functional groups. Whether the compound causes a side-reaction or not can often be judged prior to titration, by taking into consideration the functional groups present. If the substance is sensitive to oxidation or reduction it could react with iodine or iodide. Active carbonyl groups can react with methanol; iodine and sulfur dioxide can add across double bonds. Figure 5 shows titration curves with and without a side-reaction.

Hydrocarbons, halogenated hydrocarbons, alcohols, ethers, esters and other similar substances normally pose no difficulties for KF titration. Propanol or chloroform must sometimes be added to aid the solubility of long-chain compounds. Hydrocarbons that are mainly unsaturated behave inertly in the KF reagent. However, if a multiple bond is present, an addition reaction can take place which consumes iodine. Most carboxylic acids do not have to be neutralized in the same way as mineral acids. However, very strong acids, such as dichloroacetic acid or bromoacetic acid, require the addition of a buffer based on imidazole. Some carboxylic acids form esters with alcohols and therefore need to be titrated very rapidly or require a modified working medium. Working media based on ethanol esterify slower than those based on methanol. Salts of carboxylic acids can be dissolved, often with addition of formamide. Basic organic compounds such as amines require the addition of benzoic or salicylic acid to maintain the optimum pH.

Polar organic compounds such as sugars and proteins are titrated volumetrically because they are solids. These substances are dissolved by using a working medium of formamide–methanol 1:1. Warming the titration cell accelerates the dissolving process.

Aldehydes and ketones present particular difficulties for the KF titration. These substances form acetals and ketals with methanol and these reactions release a stoichiometric quantity of water. There are special reagents available for these sample types which contain alcohols that react according to the KF reaction shown in Equation (4) but which do not form acetals and ketals with the sample. Alcohols such as chloroethanol, or sterically hindered compounds such as 2-methoxypropanol, can be used as suitable alcohols. Aldehydes also react according to the bisulfite addition reaction with the KF reagent. Sulfur dioxide reacts with aldehyde groups and this reaction requires water. Therefore with conventional KF reagents a result is obtained which is too low. Special reagents for aldehydes have a reduced sulfur dioxide content to decelerate the bisulfite addition reaction and enable the KF titration to be carried out accurately. Only for very reactive aldehydes, e.g. acetaldehyde, does the side-reaction predominate.

An example of substances that are sensitive to oxidation and which react with iodine is the mercaptans. Peroxides are sensitive to reduction and react with iodide to generate iodine. There are many exceptions within each group of compounds and these can behave differently in the KF environment. It is therefore worthwhile carrying out a test titration in each case. A two-step validation is necessary with addition of standard after the titration has been carried out, as described in section 6.4, and the titration curve should be investigated.

8.2 Pharmaceutical Products

Different substance groups can be thought of under the term pharmaceuticals: raw materials, intermediates and finished products. Raw materials consist of the active substances, drugs derived from vegetable material, inorganic
salts, e.g. sodium phosphate, solvents, e.g. ethanol or polyethylene glycol, and non-active components such as saccharin and isomalt. For these materials there is often a valid, quality control method according to the relevant pharmacopeia. The methods quoted by the pharmacopeia for the determination of water content are KF titration and loss-on-drying.\(^{17–19}\)

Interference with the KF reagents can occur and can be avoided as described in section 8.1. Normally, raw materials are pure substances whose behavior can be determined by looking at their chemical structure.

If a reagent being used has a different composition to that described by the relevant pharmacopeia, it has to be validated as described in section 6.4. This validation must be carried out for each individual product being tested. Sometimes loss-on-drying is quoted as the preferred method for water determination. A KF titration can be used instead if a validation is carried out. This validation is necessary since in some cases loss-on-drying and KF titration give results that are not identical. The water content given in the specification of the raw material must also be taken into consideration. If the water content value found by the KF titration is within the specification control limit then this method can be employed.

Intermediates are mixtures of active and non-active substances that are not yet in their final state. The water content is an important quality criterion since it affects the physical characteristics of the product, such as its flow ability or its adhesiveness. In comparison to the quality requirements of raw materials, where, as a rule, only a maximum value for water content is quoted, for intermediates there is normally both an upper and lower limit specified. Tablet powders and other similar solids often display solubility problems. External extraction (section 7.1) or the KF oven (section 4.5) must then be used.

Similarly, in the finished product, the water content is an important quality criterion because it influences physical properties and storage stability. The water in tablets and capsules can be determined using either the KF oven or by external extraction. Direct titration is rarely possible. Effervescent tablets that release water and carbon dioxide are particularly problematic. A KF titration is not possible in this situation. Liquid medicine can be added direct to the titration cell. Creams and suppositories can also be added to the titration cell. If the water content is an important quality criterion since it affects the physical characteristics of the product, such as its flow ability or its adhesiveness. In comparison to the quality requirements of raw materials, where, as a rule, only a maximum value for water content is quoted, for intermediates there is normally both an upper and lower limit specified. Tablet powders and other similar solids often display solubility problems. External extraction (section 7.1) or the KF oven (section 4.5) must then be used.

8.3 Petroleum Products

Oils, lubricants and related products generally do not dissolve in the methanolic or ethanolic working medium of KF titration. In addition, they contain very small amounts of water (with the exception of crude oil), and so the determination must be carried out very accurately. Coulometry is recommended when used in conjunction with an anolyte modified specifically for oils. These special reagents contain chloroform or a long-chained alcohol to aid solubility of the oils. Sometimes xylene is added.

Crude oils must be homogenized before a sample is taken, because the water is often unevenly dispersed. Homogenization can be carried out either by a high-speed mixer or in an ultrasonic bath. Crude oil contains tar, which can stick to the electrodes. Xylene or toluene should therefore be added to the working medium of a volumetric titration and likewise to the anolyte in coulometry. In this way the tar stays in solution and cannot stick to the electrodes. Refined products such as benzene, diesel and kerosene are added to the specially modified anolytes designed for oils and fats. Disturbances with such products are not expected.

Lubricants, insulating oil and motor oils contain additives to improve their performance and increase their active life. Many of these additives cause problems for the KF titration. Antioxidants and mercaptans react with iodine, ketone groups form ketals, and metal oxides create water. Generally, the water content determined for these products by direct titration is far too high. Therefore the oven method (section 7.4) is carried out. The oil is heated at a temperature between 120 and 140°C. Coulometry is absolutely necessary because the water contents are usually in the ppm region. The water content determination of petroleum products is controlled by a large number of ASTM (American Society for Testing and Materials) and ISO standards.

8.4 Plastics

The water content of polymers, like pharmaceuticals, determines their physical characteristics and therefore it is a very important criterion. The samples to be analyzed tend to be in the form of granules, fibers or solutions. The water content is often very low and therefore coulometry is the preferred choice of instrumentation. Many of the polymers can be brought into solution by the addition of chloroform or methyl pyrrolidone and can then be titrated directly. Ketones, which are also often used as solvents for polymers, are not recommended for KF titration because they cause side-reactions (see section 8.1). Small amounts of ketone can be titrated when special reagents for ketones are used.

A volumetric titration can be tried if the polymer is in the form of a fine powder. The sample is added directly to the methanolic working medium. The methanol extracts the water from the very finely ground polymer without dissolving it.
The oven method is used for less fine powders, fibers and granules. The sample is heated to between 120 and 170 °C and its water carried over to the coulometric cell in a stream of dried gas. Since the water is released very slowly a minimum determination time of 10 min must be set on the titrator to avoid it switching off prematurely. Finding an optimum oven temperature is extremely difficult because the polymers can further polymerize and form extra water. Sometimes they can decompose at higher temperatures. It is extremely difficult to distinguish between free water and water formed during the heating process and so in practice the oven temperature is standardized for each particular type of polymer.

8.5 Foodstuffs

The water content of foodstuffs is an important quality parameter. It influences, amongst other things, taste, shelf life and appearance. An upper legal limit is set for many foods. At the same time the water content determination of food is very difficult because of the very complex material involved, and requires very careful sample preparation. Food is often a mixture of polar material, e.g. protein, and nonpolar material, e.g. fat. Additionally, ethereal oils and other chemicals that enhance the taste of a food can cause side-reactions. The water can also be distributed nonhomogeneously. Sometimes it is dissolved, sometimes suspended and sometimes, in the case of plant material, trapped in cellular structures. If the samples are heated they often easily degrade, releasing water. In such cases the results have to be carefully validated. A titration curve yields a great deal of information about possible side-reactions and the course of the titration.

Volumetric titrations are carried out almost exclusively for the titration of foodstuffs. Coulometry is only used as an exception, such as for the titration of a vegetable oil. The sample must be dissolved or very finely dispersed. A working medium mixture of methanol/formamide is used for polar ingredients such as proteins and sugars. To enable the ingredients to dissolve faster the cell used for polar ingredients such as proteins and sugars. A working medium mixture of methanol/formamide is necessary. The sample must be dissolved or very finely dispersed. High-speed mixers are state-of-the-art technology. These mixers can be set up inside the titration cell through a special opening in the lid. The sample is added and the mixer switched on for a certain set time. Short titration times and sharp EPs are possible due to the very fine dispersion of the material. Heterogeneous samples such as chocolate bars, biscuits and noodles can be investigated using this technique. Extensive coverage of the titration methods for foodstuffs can be found in Isengard.

9 INTERNATIONAL STANDARD

PROCEDURES

The International Standard ISO 760 controls the volumetric water determination according to the KF method. Reagents, instruments and procedures are quoted. Sodium tartrate-2-hydrate or water is used for the titer determination of the reagents. Since ISO 760 was written in 1978 it does not take into consideration new methods, reagents and instrumentation. There is no international standard available for the coulometric KF titration.

The general KF titration is also quoted in the various national pharmacopeias. The US Pharmacopeia and the Japanese Pharmacopeia describe the volumetric and coulometric KF titration. The European Pharmacopeia only covers the volumetric technique.

In addition to the standards that quote the general methods for the KF titration, there are also national and international standards that describe the titration of individual matrixes. Such standards, given by the American Society for Testing and Materials (ASTM), are, for example, ASTM D 1533-79 “Standard Test Method for Water in Insulation Liquids”, ASTM D 1744-83 “Standard Test Method for Water in Liquid Petroleum” and the DIN ISO 51869 “Coulometric Water Determination in Gases”.

10 COMPARISON WITH LOSS-ON-DRYING

Loss-on-drying and the KF titration do not determine the same parameters of a sample, and therefore the analytical values found can not really be compared with one another. In the KF titration the water within a sample reacts chemically. During loss-on-drying the amount of material that escapes is measured. For some samples the water content found according to KF titration and loss-on-drying is identical. Such samples would be those that release water easily and do not alter on heating. Samples belonging to this category are the salts of carboxylic acids, some inorganic salts and mineral samples. Loss-on-drying is, however, still the preferred method quoted in the pharmaceutical and food industries, where samples can yield different results in loss-on-drying and the KF titration. Results found by KF titration are, in comparison,
mainly high because the water is fully extracted and reacted. Foodstuffs often yield higher results due to the degradation that often takes place under the conditions of loss-on-drying.

15. ‘Application Bulletins’, Metrohm Ltd, Herisau, Switzerland. (email: sales@metrohm.ch)

Descriptions of analytical methods and instrumental techniques are found in an astonishing variety of resources. Because of this wide variety of sources and the extensive time period over which they have been published, developing an effective literature searching methodology is absolutely essential for students, research faculty, and practicing chemists. This article covers traditional methodologies and basic resources. In addition, recent widespread adoption of electronic journals and reference works, plus the virtually universal adoption of Google searching, are substantially transforming literature searching methodology.

1 INTRODUCTION

Descriptions of analytical methods and instrumental techniques are found in an astonishing variety of resources. Books, handbooks, journal articles, technical reports, theses, patents, standards, protocols, or encyclopedias may contain a specific method or describe a methodology appropriate for an analytical problem. Because of this wide variety of sources and the extensive time period over which they have been published, developing an effective literature searching methodology is absolutely essential for students, research faculty, and practicing chemists. Developing this methodology, fortunately, is largely a matter of guidance and extensive practice.

Guidance is often provided by colleagues, textbooks, and current awareness readings, but needs to be supplemented by interacting with knowledgeable librarians, making use of literature guides, and extensive practice. Many technical libraries have former bench chemists on their staff and many academic libraries require an appropriate undergraduate degree for their subject-specialist librarians. Asking for help can be an excellent...
technique both for getting started and for learning about new and unusual resources.

Practice is necessary because of the difficulty, often encountered, in answering the simple questions, “where do I start?” or “where do I look next”? The Encyclopedia of Analytical Chemistry (EAC) is an obvious first answer to either of these questions, since this monumental work provides professional-level coverage of all aspects of analytical chemistry, from theory and instrumentation through all applications in all matrices. Availability of the EAC, however, does not obviate the need for a comprehensive understanding of the basic fundamentals of literature searching and regular practice using the full range of analytical chemistry resources.

The fundamentals of literature searching include a working knowledge of the cataloging and indexing practices in both library catalogs and indexing and abstracting services; a thorough familiarity with the structure and interrelationships of the literature of analytical chemistry; experience in using the various resources; a well-developed discipline of current awareness; and a knowledge of the Internet’s strengths and weaknesses as a search tool. These factors are essential for the development of an effective literature searching methodology.

Recently, approaches to literature searching have undergone a dramatic transformation since the print publication of the EAC. The Internet and, specifically, Google and Google Scholar (GS) have been almost completely transformative. In fact, “conservatively, ninety-five percent of all scholarly inquiries start at Google.”(4)

Given this situation, traditional sources of information and their electronic equivalents are increasingly vulnerable to being marginalized by freely available Internet resources. Chemical Abstracts (CA) and SciFinder/SciFinder Scholar continue to provide a level of excellence in the indexing of chemistry-related material.(5) In addition, efforts are currently under way in many libraries to develop “federated searching”, which is a process whereby simultaneous searching of multiple electronic resources can be accomplished. This emerging feature is viewed as a portal, since the results can be merged, deduplicated, and sorted, in contrast to a web search engine, such as Google, which is limited by crawler technology and lack of access to deep web documents.(6)

2 CATALOGING AND INDEXING SPECIFICITY

One of the basic fundamentals of developing a methodology for searching the literature of any subject is an understanding of the concept of “cataloging or indexing specificity”. In library card catalogs and their successor OPACs (Online Public Access Catalogs), books are cataloged as specifically as they are written.

An excellent example is Kuwana’s three-volume set on Physical Methods in Modern Chemical Analysis,(1) which has chapters on transform techniques, electrochemical characterizations, high-performance liquid chromatography, X-ray diffraction methods, gas chromatography, and flame and plasma emission analysis. It is only retrievable (by subject) in library catalogs by searching the keywords in the title or “chemistry, analytic” as a subject heading. The inability to retrieve this book by searching on chapter-title words or subject terms related to the individual analytical techniques is obviously somewhat confusing. This is especially true when there are monographs on each of these techniques that are easily located by searching on keywords and subject terms in a library catalog. A further example of the specificity problem is exemplified by books dealing with “chronoamperometry”, which may also be found cataloged or indexed only under “amperometry”, “voltammetry”, or “analysis, electrochemistry”.

The practice of indexing specificity is carried to its extreme, however, in the cataloging of the encyclopedia,
treatise, or reference set. This concept explains the single subject headings: “chemistry, analytic – encyclopedias” for Encyclopedia of Analytical Science, “chemistry, analytic” for Treatise on Analytical Chemistry, and “chemistry – manipulation” for Physical Methods of Chemistry, in library catalogs. All three of these titles are comprehensive multivolume works that cover virtually all aspects of their corresponding subject fields. As an aid to searching library catalogs and OPACs at a more general level, the Library of Congress publishes Library of Congress Subject Headings, which is in its 30th edition.\(^{(2)}\) This book provides broader terms (BT), narrower terms (NT), and related terms (RT) for a wide variety of subject concepts.

In Chemical Abstracts Service (CAS),\(^{(3)}\) which indexes journal articles, patents, and so on, the specificity problem is not as severe, since many multivolume works are indexed as separate volumes or at the chapter level. For example, each of the chapters in volumes 1 and 2 of Physical Methods in Modern Analytical Chemistry is indexed separately. Coverage issues, however, complicate the situation. SciFinder/SciFinder Scholar\(^{(1)}\) has replaced CAS Online, and combines CAplus, CAS Registry, CASREACT, CHEMCATS, and CHEMLIST.

While SciFinder/SciFinder Scholar can be searched with title and CAS abstract keywords, CAS index terms are selected from “new” information reported in the document. This is in contrast to the expanded keyword searching (title and author abstract keywords, author supplied keywords, and significant keywords from the titles of an article’s references) that is possible in the Web of Science, the web version of the Science Citation Index (SCI),\(^{(4)}\) another journal-article database. This is obviously a subtle distinction, and is pointed out to emphasize the need to search multiple databases in a comprehensive literature retrieval.

In either SciFinder/SciFinder Scholar or print, “The fact that a substance or concept, reported in a document, is not in itself new does not mean that it will not be indexed, only that the indexing will focus on the novel aspects. However, when long lists of known substances and accompanying previously published experimental data are reported, but the author’s main interest is in some property or source of the substances, the substances are not indexed specifically but receive General (Subject Index) entries only.”\(^{(5)}\)

In addition, “CA chooses the most specific term possible as an index heading. Thus, separate entries would be found at “fluorometers” and “phosphorimeters”, when an original document discusses both of these processes, rather than a single entry at “spectrometers”. However, a review article on spectrometers (that includes examples of fluorometers and phosphorimeters) may only be assigned the more general index term. As an aid to searching at a more general level, CA provides “Hierarchies of General Subject Headings”.\(^{(6)}\)

Today the importance of cataloging and indexing specificity is underscored by what is widely known as search engine chaos. Despite the ability of Google/Google Scholar to retrieve a few pertinent articles or web sites, library catalogs and professionally indexed databases (e.g. CA) continue to be essential for comprehensive research needs.

**3 THE LITERATURE OF ANALYTICAL CHEMISTRY**

One of the obvious difficulties in approaching the literature of analytical chemistry is its enormity. The 100-fold growth in the annual output of CA from about 10 K abstracts in 1907 to over 1 M abstracts in 2007 is an excellent indicator of the need for a carefully developed search methodology.

Before approaching the specialized literature of analytical chemistry, however, it is essential to use and become familiar with basic reference and general chemical resources (the importance of developing this skill cannot be overemphasized). The vast majority of questions in a public library, for example, can be answered by referring to an encyclopedia, for example, Encyclopedia Britannica\(^{(1)}\); a dictionary, for example, Webster’s Third New International Dictionary\(^{(2)}\); an almanac, for example, Information Please Almanac\(^{(3)}\);
or an atlas/gazetteer, for example, *The Times Atlas of the World* \(^{(4)} \) or *Merriam-Webster’s Geographical Dictionary*. \(^{(5)} \)

Many basic chemistry questions can be answered by an encyclopedia, for example, *Encyclopedia of Physical Science and Technology* \(^{(6)} \) or *Encyclopedia of Chemical Technology* \(^{(7)} \); a dictionary, for example, *The Condensed Chemical Dictionary* \(^{(8)} \); a data book, for example, *Handbook of Chemistry and Physics* \(^{(9)} \) or *Merck Index* \(^{(10)} \); or a catalog/structure index, for example, *Aldrich Catalog* \(^{(11)} \) *Aldrich Structure Index*, \(^{(12)} \) or *Dictionary of Organic Chemistry*. \(^{(13)} \)

Extending this analogy to analytical chemistry requires familiarity with encyclopedias, for example, *Encyclopedia of Analytical Science* \(^{(14)} \) or the *Instrumentation and Applications* section of EAC \((this\ publication);\) dictionaries, for example, *Dictionary of Spectroscopy* \(^{(15)} \) or *Dictionary of Chromatography* \(^{(16)} \); data books, for example, *Critical Stability Constants* \(^{(17)} \) or *Tables of Standard Electrode Potentials* \(^{(18)} \); and compilations of analytical methods and instrumental techniques, for example, *Treatise on Analytical Chemistry*. \(^{(19)} \)

Some information formerly found in general encyclopedias, yearbooks, almanacs, and dictionaries can be easily found through Google or Yahoo. \(^{(20)} \) This partially obviates the need to be thoroughly familiar with the basic reference and general chemical resources. Many of the specialized chemical references continue to retain their importance, with many appearing in new editions and as associated electronic versions. Electronic versions are generally sold on a subscription basis that includes regular updating.

*Wikipedia* \(^{(21)} \) is a unique attempt to provide encyclopedic information. It is reputed to be the “biggest multilingual free-content encyclopedia on the Internet, with over 7 million articles in over 200 languages, and still growing.” *Wikipedia* \(^{(21)} \) is written collaboratively by volunteers from around the world. *Citizendium* \(^{(22)} \) is an attempt to offer an “edited” counterpart to *Wikipedia*. *Knowel* \(^{(23)} \) is a unique service that aggregates reference works, including handbooks and databases, in 19 subject areas, including chemistry. There are currently 18 “analytical chemistry” titles, which are freely searchable; however, the electronic content is only available to subscribers.

There are also a variety of electronic “news” magazines and web sites, such as *SpectroscopyNow*, *SeparationsNow*, \(^{(24)} \) *News Analytic*, \(^{(25)} \) the “analytical highlights” section of Chemistry & Industry, \(^{(26)} \) the Royal Society of Chemistry (RSC) *Analytical Gateway*, \(^{(27)} \) the American Chemical Society (ACS) Division of Analytical Chemistry’s Analytical Sciences web site, \(^{(28)} \) and the *ChemLin Virtual Library*. \(^{(29)} \)

Progressing to the full range of analytical chemistry literature requires familiarity with textbooks and sources of official analytical methods or protocols, encyclopedias, reference books and treatises, review articles and specialist monographs, journal articles, conference papers, technical reports, theses and patents, abstracting and indexing resources, comprehensive data books, and dictionaries, catalogs, and directories.

Thus, the crux of developing an efficient literature searching methodology is a thorough familiarity with the wide variety of information resources, through consultation and extensive practice, so that quickly locating an appropriate resource for a particular problem becomes routine.

Perhaps the most important concept the reader must learn is when to begin searching CA. \(^{(30)} \) Because of this resource’s comprehensive coverage, it is often difficult to determine when to progress beyond what can quickly be found in library catalogs and easily available reference sources and begin a more formal search of the literature. For this reason, it is absolutely essential to become familiar with the wealth of secondary literature resources.

The description of the analytical chemistry literature that follows progresses from the secondary literature (textbook and official analytical methods; encyclopedias, reference books and treatises; review journals, research monographs, and monographic series) to the primary literature (journal articles, conference papers, technical reports, theses and patents) and their indexing and abstracting services. This is followed by the tertiary and miscellaneous literature (data compilations; dictionaries, catalogs, directories; Internet search engines and guides; and miscellaneous tips). This approach allows readers to orient themselves quickly and makes the next step, for any given problem, much more obvious.

**REFERENCES**

10. Merck Index, 14th edition, Merck Manuals, Whitehouse Station, 2006 (Includes a companion text searchable CD-ROM, that also includes over 1000 monographs from the 12th and 13th editions that are not available in the print copies of the 14th edition).

4 TEXTBOOK AND OFFICIAL ANALYTICAL METHODS

Analysis and testing are frequent operations in chemical laboratories. For many routine purposes, textbook methods may be adequate; however, in certain circumstances, an official or standard method (SM) is required. World Wide Web (WWW) sites are provided to allow readers to check for up-to-date information from these resources. Books and reference works that fit into this category are listed here. Current and archival official methods are now both generally available on the WWW.

FURTHER READING

1. D.C. Harris, ed, Quantitative Chemical Analysis, 7th edition, Freeman, 2006. This is the definitive modern textbook of quantitative analysis, which includes a final chapter of experiments. http://bcs.whfreeman.com/qca7e/
2. D.A. Skoog, ed, Fundamentals of Analytical Chemistry, 8th edition, Saunders, 2004. This is an introductory textbook designed primarily for a one or two semester course for chemistry majors, with selected methods of analysis in the final chapter.

Vogel is intended as a comprehensive textbook for both students and practicing analytical chemists and contains an extensive listing of specific procedures, albeit without references to the original literature.

This final edition, while dated, is in five parts, largely devoted to specific applications. Analysis of the chemical elements is covered in volume 1, classes of substances in volume 2, and instrumental methods in volume 3.

The ASTM standards continue publication in print, but have added electronic access to individual volumes, an online basic subscription to active standards, and an online plus subscription which also shows changes from a previous edition, previous editions, and withdrawn standards. http://www.astm.org/cgi-bin/SoftCart.exe/STORE/standardsearch.shtml?E+mystore

Official methods have been developed by federal, state, local, and industrial scientists for products related both to agriculture and public health and for enforcing laws and regulations. http://eoma.aoac.org/

This includes the latest and most important methods required by several major environmental statutes. A glossary of terms and abbreviations, as well as an EPA regulatory contact directory, is included.

This contains over 1700 analyte/method summaries with a double table of contents that lists chemical names/CAS registry numbers in alphabetical order and CAS registry numbers/names in numerical order. http://www.environetbase.com/ejournals/books/book_summary/summary.asp?id=80

CPFAC covers four main analyte types: volatile organic compounds, semivolatile/nonvolatile organic compounds, metals, and radionuclides. It is available in either a loose-leaf or CD-ROM format and is updated quarterly.

5 ENCYCLOPEDIAS, REFERENCE BOOKS, AND TREATISES

For more specialized problems, when textbook or SM are either unavailable or inappropriate, encyclopedias, reference books, and treatises provide comprehensive coverage of analytical methods and instrumental techniques. The importance of becoming familiar with these publications cannot be overemphasized. These publications often refer to specialized monographs that may also be found in library catalogs by searching on title keywords or appropriate subject headings. Many encyclopedias and reference books are now also available, as annual subscriptions, on the WWW.

FURTHER READING

Composed of over 280 articles in eight volumes, it provides the background information necessary to prepare and evaluate environmental compliance documentation as well as laboratory protocols for pollutant analysis.

The 51 chapters are grouped in the following sections:

- Introduction (sample preparation, laboratory automation, etc.)
• Separation methods/Qualitative optical spectroscopic methods
• Quantitative optical spectroscopic methods/Mass spectrometry
• Electroanalytical techniques/Microscopic and surface analysis
• Polymer analysis
• CD-ROM technique selection software program.

The articles cover three broad areas:

- Techniques (e.g. spot tests, mass spectrometry, chemometrics)
- Applications (e.g. asbestos, pharmaceuticals, pigments, forensics)
- Analytes (e.g. aluminum, cholesterol, nucleic acids).

http://www.sciencedirect.com/science/reference works/9780123693976

There are sections covering, amongst others, the following areas:

- Sample preparation
- Separation, gravimetric, volumetric, and chromatographic methods
- Instrumental methods
- Organic, water, and geological/inorganic analysis
- Statistics.

The printed version comprises 28 alphabetically arranged volumes, 8 volumes on general aspects such as chemical engineering, industrial safety, and analytical methods, and a cumulative index volume with more than 80,000 carefully selected keywords. It also contains a German–English dictionary of technical terms. An alphabetical listing of the contents is available on the web site.

- Vol. B5 Analytical Methods – I

The analytical methods sections discuss commonly used procedures in both process engineering and research activities.

http://mrw.interscience.wiley.com/emrw/97835273-06732/home/

This encyclopedia focuses on the significant aspects of chemical substances, industrial processes, unit operations, and fundamental concepts. It includes charts, graphs, and tables and provides CAS registry numbers for substances.

http://www.mrw.interscience.wiley.com/emrw/0471-238961/home

This is a compilation of practical descriptions of the most frequently used instrumental analytical methods, with information on sensitivity and applicability, and advice on how to optimize the measurements. Contents include “chapters” on all the standard instrumental techniques as well as the following: laboratory use of computers; continuous-flow analyzers; photoacoustic spectroscopy; techniques of chiroptical spectroscopy; and capillary electrophoresis.

6 REVIEW JOURNALS, RESEARCH MONOGRAPHS, AND MONOGRAPHIC SERIES

The primary role of both review articles (including plenary conference lectures) and chapters in research monographs is to summarize new research on a particular topic that updates information found in textbooks, encyclopedias, or treatises. The review is expected both to summarize and evaluate this information and to provide a bibliography of the original sources.

Locating review articles is fairly straightforward, because both CA and the Web of Science use “review” as a subject term. In the web of Science, a review article is defined as either having 100 or more references, or appearing in a review publication or a review section of a journal, or if review or overview appears in the title, or the abstract states that it is a review or survey. In CA, trained editorial staff categorize review articles on the basis of an assessment of the content. A review may be an article, a bibliography, a discussion, a portion of a book, and so on, and it may be critical or noncritical.

Locating specialized monographs, chapters in research monographs and plenary conference lectures, however, can be difficult owing to the absence of suitable descriptions of monographic works and conference proceedings in library catalogs. As mentioned previously, multivolume works may receive only a single subject entry in library catalogs, books in series may only be cataloged under the series title (without title or subject entries for individual volumes), and plenary conference lectures are only cataloged under the conference title. Finding these publications requires imaginative searching of library catalogs, followed by a search of CA and limiting the search to “book” as a document type or “review” as a keyword. Google is an alternative route for locating such material.

Maintaining a current awareness of newly published review material requires familiarity with a wide variety of bibliographic tools. These include the following electronic resources:

- Amazon http://www.amazon.com/
- Baker-Taylor’s monthly listing of new academic books http://www.baker-taylor.com/Academia/Academia.html
- Index to Chemical Education Resources (textbooks) from the Journal of Chemical Education http://www.ums.edu/~chemist/books/texts.html
- Comprehensive library catalogs such as the University of California’s Melvyl http://www.melvyl.ucop.edu/ and Linda Hall’s Leonardo http://opac.lhl.lib.mo.us/.

6.1 Review Journals

1. American Chemical Society, Analytical Chemistry, http://pubs.acs.org/journals/ancham/index.html. Fundamental Reviews and Application Reviews are published in alternate years as the June 15 issue. Starting with the first issue of 2006, Analytical Chemistry’s News, Features, and Departments (previously called the A-Pages) are integrated with the research papers into one page-numbering scheme.

### 6.2 Research Monographs

Lists of specialized monographs are generally included in the appendices of analytical chemistry textbooks and reference books. Recent publications are listed in the Book Buyer’s Guide supplement to the *Journal of Chemical Education*, and the *Subject Guide to Books in Print* (published annually by R.R. Bowker). Subject searching for books with the subject “analytical chemistry” is also available on the WWW at (http://www.amazon.com). Amazon.com also provides a list of “50 best sellers” in a wide variety of categories. The titles of the top five analytical chemistry books, in terms of sales, as of December 2007 are:

### FURTHER READING

### 6.3 Research Monographic Series

In addition to individually published research monographs, there are a number of continuing research monographic series that routinely publish books on analytical topics. As mentioned previously, libraries may only catalog these books in series under their series title and not provide keywords or subject headings for each individual volume. Thus, searching under the series title is very strongly recommended, if the individual volume is not found.

7 PRIMARY LITERATURE (JOURNAL ARTICLES, CONFERENCE PAPERS, TECHNICAL REPORTS, THESES, AND PATENTS)

These seemingly disparate types of publication are included in the broadest definition of the primary literature. The formal primary literature consists of peer-reviewed journal articles, which can be reliably expected to present data and procedures upon which further research can be conducted. The informal primary literature includes conference papers, technical reports, theses and patents, which are not peer-reviewed and, in many cases, should be considered the raw material for the formal primary literature. Searching for information in these resources is greatly facilitated by the indexing and abstracting tools described in the next section.

7.1 Journal Articles

Analytical chemistry research journals, as defined by Institute for Scientific Information (ISI), are listed below with their journal ranking data and sorted by “impact factor” (Table 1). Analytical articles, however, appear in virtually all chemistry journals.

A consistent habit of reading the current analytical literature is greatly facilitated by perusing the high-impact titles (Analytical Chemistry, TrAC, etc.) and using current awareness services such as Current Contents http://www.isinet.com/prodserv/cc/cchp.html (which is available both in print and on line) and CA Selects http://www.cas.org/PRINTED/caselects.html. In its “Highlights Section”, Chemistry and Industry http://ci.mond.org/ reviews the most significant new papers published in the scientific journals (new materials and analytical chemistry in the odd-numbered issues).

Journal articles have undergone a major transformation as they are now widely available on the WWW (albeit generally requiring a subscription). Open access journals are growing in number, although the concept

<table>

of author payments is not widely popular. A wide variety of updating options is now available on each journal’s web site, along with articles that have been accepted but not assigned to a specific journal issue. An extensive listing of ‘analytical chemistry’ journals is given at CiteSeer.(5)

REFERENCES

7.2 Conference Papers
Collections of conference papers are considered in this context, since they are very similar to a focused journal issue. In fact, many conference papers are collected and published as special issues in a wide variety of research journals. In this case, papers are indexed and abstracted as if they were journal articles. Individually published conference proceedings, however, are a special problem. Literature citations to conference proceedings rarely correspond to the way in which they are listed in library catalogs. The availability of the British Library’s Document Supply Centre Conference Index on the WWW(1) and CISTI Catalog(2), however, greatly assists in locating the necessary bibliographic information. Once the official conference name or conference title is known, libraries holding the volume can be found in CASSI (Chemical Abstracts Service Source Index) or WorldCat (http://www.worldcat.org/). In many cases, recent conferences also have their own web page, which may include abstracts of the presentations. These can be found by searching for keywords and the conference location on an Internet search engine such as Google. Both the Eastern Analytical Symposium (http://www.eas.org) and the Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (http://www.pittcon.org) have web sites.

REFERENCES

7.3 Technical Reports
In addition to peer-reviewed journal articles, technical reports are an accepted method of publishing research results in fields such as environmental engineering, aerospace engineering, and energy research. Technical reports are also a necessary requirement for reporting the results of government-sponsored research. These submissions to the National Technical Information Service (NTIS) database are often progress reports and may simply be references to a published journal article. Searching for technical reports is usually based on a citation to an author or report number. The Stanford University Engineering Library has posted a ‘How do I find?’ web page for technical reports: http://www.sul.stanford.edu/collect/tech rpt.html.

FURTHER READING
   This collection covers government-sponsored US and worldwide scientific, technical engineering, and business-related publications. It includes references to the 3M publications and technical reports that NTIS has received from Government agencies since 1964 with a few exceptions.
   The DTIC Technical Report collection includes all unclassified and unlimited technical report citations to full-text reports since 1965. It is freely searchable.
   The DOE database contains references to all DOE-sponsored scientific and technical reports sent to Government Printing Office (GPO) Depository Libraries, beginning with January 1, 1994. It is supplemented by the access to full-text DOE research and development reports in physics, chemistry, materials, biology, environmental sciences, energy technologies, etc. from 1996 onward.
   The NTRS provides access to NASA’s (National Aeronautics and Space Administration) current and historical technical literature – approximately 500 K aerospace-related citations, 90 K full-text electronic documents, and 111 K images and videos. Information includes conference papers, images, journal articles, photos, meeting papers, movies, patents, research
reports, and technical videos. NTRS integrates three separate information collections through a common search interface:

- NASA Collection: Citations and documents from 1958 to date.
- NIX Collection: Citations and images, photos, movies and videos downloaded from the NASA Image eXchange.

5. National Service Center for Environmental Publications NSCEP/NEPIS, http://www.epa.gov/ncepihom/. EPA’s Gateway to 7000 in stock and 26 000 digital titles available free of charge to search and retrieve, download, print and/or order.

7.4 Theses

Virtually, all theses from US and Canadian universities (as well as an increasing number of European institutions) are deposited with ProQuest Digital Dissertations (formerly University Microfilms), which publishes Dissertation Abstracts International. Access to the complete file from 1871 is available on the WWW (a fee-based service, which is available in most academic libraries).

In addition, CA indexes (but does not abstract) chemical theses from records provided by ProQuest, NDLDT (Networked Digital Library of Theses and Dissertations) is a project that facilitates the development of institutional databases of electronic theses, whose records can be harvested by Google.

REFERENCES

7.5 Patents

The patent literature is a very important albeit often underutilized resource, especially in an academic setting. Many of the patent documents referenced in CA are European or Japanese patent applications because these applications are publicly available prior to the final granted patent. This results in a family of patent documents from different countries. Locating a granted US patent from, for example, a European patent (EP) application number is facilitated by the CA Patent Index (cumulated in SciFinder/SciFinder Scholar), as well as other commercial vendors. Over 126 K patent documents are currently referenced in CA each year and of these, over 1300 were classified in the Inorganic Analytical Chemistry or Organic Analytical Chemistry sections in 1997. A sampling of the titles of these patents is given in Table 2.

While patents are extensively covered in CA, the World Patent Index, and Claims (all fee-based services on STN International, as well as other commercial vendors), there are also several US patent databases available, at no cost, on the WWW. Each of these free services provides something a little different, in searching or display, so it is worth checking each of them out.

FURTHER READING

1. Esp@cenet database, http://ep.espacenet.com/. Provides access to worldwide patents and offers full-text PDF downloads for patents of less than 50 pages.

8 ABSTRACTING AND INDEXING SERVICES

An abstract is a brief summary or digest of the most significant results reported in a primary source. The services described below are clearly indispensable for

<table>

</table>
collecting materials to write a review of a topic, to locate a specific fact or technique not easily found in secondary sources, and to follow current research advances.

The author abstracts are being increasingly used by the major services. CA (see Section 8.1), while depending on volunteer chemists as abstractors in the past (especially for articles published in Cyrillic and oriental languages), now employs staff abstractors and is increasing its use of author abstracts. This is especially true for ACS publications that provide electronic versions that are added to the CAPlus database ASAP (i.e. as soon as publishable). CAPlus is an enhanced version of the CA online database. ASAP is a new feature of the ACS journal’s web editions (http://pubs.acs.org/) that allows the posting of articles prior to formal publication.

ISI’s Web of Science, (see Section 8.2) which includes abstracts for about 65% of the articles indexed since 1991, uses the author’s abstract exclusively.

Analytical Abstracts (see Section 8.3), however, because of its specialized perspective, does not use author abstracts. All of their abstracts are written in-house, from an analytical perspective, giving as much analytical detail as is practical.

The currency of these three services varies widely. The CAPlus online file is updated daily, and includes articles from ACS journals before they are published in print. Web of Science generally depends on the print journal and is usually about 3–4 weeks behind the current journal issue, with CA generally about 3–4 months behind and Analytical Abstracts generally about 7–8 months behind.

UnCover (see Section 8.4) and Institut de l’Information Scientifique et Technique (INIST) (see Section 8.5) are journal-article databases that are freely searchable on the WWW. They both are limited to brief bibliographic details and do not provide abstracts.

8.1 Chemical Abstracts

CA (http://www.cas.org/expertise/cascontent/caplus/index.html) currently abstracts over 1 million items (journal articles, patents, dissertations, reports, book chapters and reviews), of which only about 10 K are specifically classified each year as either inorganic or organic analytical chemistry. This, however, grossly underestimates their coverage since analysis articles are also classified in many other subject sections (e.g., drugs, enzymes, fossils, fuels, and rocks).

CA, in print, is issued weekly with semiannual indexes, author, general subject (molecular) formula, chemical substance (names), and patent (numbers) that are cumulated every 5 years. The companion fee-based online service covers the chemical literature from 1967 to date and currently includes over 75% of all the abstracts published since 1907.

The key to effective use of CA is a thorough familiarity with the Index Guide. Each edition (e.g. 1992–1996) of the Index Guide is intended for use with the corresponding General Subject Index and Chemical Substance Index for that time period. The CA Index Guide is composed of a main body that contains cross-references, indexing notes, valid general subject index headings, and structural diagrams for cyclic and acyclic stereoparent compounds, as well as four appendices that describe the organization and interrelationship of subject terms and the rules for naming chemical compounds.

The entry under Analysis, in the 1997 CA Index Guide, lists both NT (chromatography, ellipsometry, kinetic analysis, polarimetry, titration) and RT (analytical numbers, gas sensors, sampling) and is supplemented by the entry in the CA General Subject Index, shown below.

8.1.1 Analysis

Studies of chemical analysis in only a broad sense are indexed at this heading.

More specific aspects are indexed when possible under hierarchically narrower headings; see Hierarchy 2, Appendix I of the Index Guide. For studies on the analysis of specific substances, see headings for those substances in the Chemical Substance Index. For classes of substances, such as amines, proteins, or minerals, see headings for those classes in the General Subject Index.

The importance of using the Index Guide, specifically the one for the time period being searched, cannot be overemphasized. For example, this is where you will find that diethyl ether is indexed as Ethane, 1,1′-oxybis- and that prior to 1997, the various types of chromatography, e.g. gas chromatography and paper chromatography, were assigned inverted General Subject Index headings, e.g. Chromatography, gas and Chromatography, paper.

The main difference between searching the print and online versions of CA is the use of CA Registry Numbers in the online CA file and the use of inverted CA Index Names in the print Chemical Substance Index. The online Registry File provides the links between the registry numbers and index names.

A compendium of instructional materials for searching CA (both print and on line) is available at http://www.indiana.edu/~cheminfo/cciiim31.html.

8.2 Web of Science

Web of Science (http://scientific.thomson.com/products/wos/) is ISI’s web product, now a component of ISI’s Web of Knowledge. It includes the SCI, the Social Science Citation Index (SSCI), and the Arts and Humanities
Citation Index (AHCI). Web of Science is exclusively a journal-article database, but this definition includes some serial and review publications (e.g. Materials Science Forum, Advances in Chemical Physics, Annual Review of Biochemistry). With the Century of Science initiative, approximately 850,000 fully indexed journal articles have been added from 262 scientific journals published in the first half of the twentieth century.

The SCI continues to be available as a print publication. It serves as a very useful journal-article index (the Source Index is the author index and the Permuterm Index is the subject index), with the Citation Index providing an author index to articles that have been cited in more recent articles.

The Web of Science provides the same search capabilities, but expands the subject searching to include author keywords, words from the abstract (if present), and significant words from the titles of related articles (keywords plus). Web of Science also allows searching on journal titles and significant elements from an author's address (e.g. zipcodes) as well as providing links to related articles (i.e. articles that cite articles in common).

8.3 Analytical Abstracts

Analytical Abstracts (http://www.rsc.org/Publishing/CurrentAwareness/AA/index.asp) has nearly 400 K records. It is available in a monthly print version with a subject index that is cumulated annually along with an author index. An electronic fee-based version is also available covering 1980+ with abstracts since 1984. Analytical Abstracts covers the major analytical journals (and some of the more specialized journals) as well as British and Australian Standards, books, and some manufacturers' application notes.

One of the major features of Analytical Abstracts is the indexing. Index terms are qualified to denote the analyte (the substance being determined, detected, etc.), the matrix (the sample being analyzed) and the concept (the technique used, properties such as pH, humidity, chemometric technique, etc.).

The electronic version of Analytical Abstracts is a relatively small database (about 250 K records) compared to CA (15.6 M records) and the Web of Science (9.7 M records) and is limited to journal articles (98%), books (1%), and reports (1%). By comparison, CA and Web of Science, contain over 900 K and 180 K records that mention either analysis or analytical chemistry, respectively.

Because of the careful indexing and abstracting, Analytical Abstracts is not as up-to-date as either CA or Web of Science.

8.4 Ingenta Connect (Previously Uncover)

Ingenta Connect (http://www.ingentaconnect.com/) is a database of current article information taken from well over 17,000 multidisciplinary journals (including over 350 of the major chemistry journals) and contains brief descriptive information for over 23,000,000 articles that have appeared since the autumn of 1988. Ingenta has an automated alerting service that delivers the table of contents of your favorite periodicals directly to your e-mail box.

8.5 Institut de l'Information Scientifique et Technique

INIST (http://articlesciences.inist.fr/) is a journal-article database, sponsored by the Centre National De La Recherche Scientifique (CNRS) in France. It includes records for over 4.5 M articles since 1990. It has both an English and French version. While explicit journal coverage is not readily available, the fact that INIST indexes 49 journals with “analytical” in the title suggests that its coverage in the sciences is comprehensive.

8.6 Google Scholar

GS (http://scholar.google.com/) is a freely accessible web search engine that indexes the full text of scholarly literature across a variety of formats and disciplines. It is similar, albeit far more comprehensive, than Scirus, CiteSeer, and getCITED. GS is also similar to Scopus and Web of Science, but lacks both a structured presentation of results and any source information. GS also provides a citation index analogous to Scopus and Web of Science.

9 DATA COMPILATIONS

Data compilations have evolved from the primarily descriptive individual efforts of Beilstein (Handbook of Organic Chemistry), Gmelin (Handbook of Inorganic Chemistry), and Landolt–Bornstein (Numerical Data and Functions in Physics, Chemistry, Astronomy, Geophysics and Technology) to the International Critical Tables (ICT) (Numerical Data of Physics, Chemistry, and Technology), which was the first comprehensive data compilation subjected to rigorous evaluation by cooperating experts. Following publication of the ICT in 1933, an increase in the publication of specialized data compilations complemented completion of the sixth edition of Landolt–Bornstein, which appeared in 28 volumes between 1950 and 1980, and the Landolt–Bornstein New Series (Numerical Data and Functional Relationships in Science and Technology), which is a work in progress.

The important distinction between the named compilations (which are described in depth by Wiggins in
Chemical Information Sources, McGraw-Hill, New York, 1991) is that Beilstein (organic compounds) and Gmelin (inorganic/organometallic compounds) are organized by chemical compounds and Landolt–Bronstein is organized by physical property.

The CRC Handbook of Chemistry and Physics, under the editorship of David Lide, is an obvious first choice for basic property data. It also provides information on sources of additional data for each property. It is available in print, on CD-ROM, and on the WWW (13). Knovel Critical Tables (14), which are freely available to academic institutions, complement the physical-property sections of the HCP. Beilstein and Gmelin are now also searchable in conjunction with a wide variety of specialized databases through DiscoveryGate (15). Landolt–Bornstein has added a freely available electronic index (16). Chemical Abstracts is adding a wide variety of both experimental (including spectra) and predicted physical properties (17). The US National Institute for Standards and Technology (NIST) offers the freely available NIST Chemistry WebBook, which provides a wide variety of spectra (18). The Mineralogy Database (19) offers data on over 4.4 K mineral species.

   This web site includes information on the following topics:
   - Electrochemistry and related subjects on the Internet WWW Sites
   - Newsgroups/mailing lists/frequently asked questions
   - Public domain information on the Internet (bibliographies/software/physical and chemical data)
   - Popular science information
   - Review chapters (index of 2000 items)
   - Books (index of 750 items)
   - Proceedings volumes (index of 450 items)
   - Graduate schools (300 listings from over 45 countries)
   - Scientific and technical societies
   - Scientific and technical journals
   - Handbooks, bibliographies
   - Nomenclature, standards, etc.
   - Meetings.

   Useful for finding CA Index Names.

   Provides spectra and Beilstein references.

   Includes both procedures and numerical data.

7. National Institute of Standards and Technology (NIST) Critically Selected Stability Constants of Metal Complexes (computer file) Version 8.0, NIST Standard Reference Database 46, NIST, Gaithersburg, MD.

   Includes general physical properties and analytical uses for all 500 reagent chemicals.

   Spectra, physical constants, crystal structures, sequence databases.

    Physical property data and two-dimensional chemical structures for common chemicals. Indexes over 75K unique substances from over 350 chemical information sites.

11. Mineralogy Database, David Barthelmy http://www.webmineral.com
    Database of over 4.4K individual mineral species; crystallography, chemical composition, physical, and optical properties.

    Using a periodic table arrangement, extensive data is provided for each chemical element.

16. Landolt–Bornstein Substance/Property Index http://lb.chemie.uni-hamburg.de/index.html

10 DICTIONARIES, CATALOGS, DIRECTORIES, AND SO ON

There are a number of specialized dictionaries, catalogs, and directories related to analytical chemistry, which can be very useful. For example, since literature references in journal articles only include journal abbreviations, and full titles are necessary for searching library catalogs, the CASSI (http://www.cas.org/PRINTED/cassi.html) provides a letter-by-letter alphabetical journal abbreviation index to full journal titles.

Of late, many of these dictionaries have not been updated with new editions, perhaps as a testament to the ubiquity of Google’s define option. Some new electronic resources include IATE (Inter-Active Terminology for Europe), which is used for translating a term from one European language to another. BioABACUS (Biotechnology Abbreviation and Acronym Uncovering Service) is a searchable database of abbreviations and acronyms in Biotechnology.

11 INTERNET SEARCH ENGINES AND GUIDES

The transition from hand-set type and print indexes (in the 1950s and 1960s), through computer composition and online searching (in the 1970s and 1980s), to web-based publication and Internet search engines (in the 1990s) has been truly revolutionary. Current estimates suggest that there are ~30B pages on the WWW(1) and Google is the preeminent Web search engine for most WWW users.(2)

If the Internet were a book, Search Engines (e.g. Google) would be the index and Internet Guides (e.g. Yahoo) would be the contents pages. To maintain currency, given the dynamic nature of the WWW, search engines are constantly running software called “robots” or “crawlers” that read entire web sites and
update their index entries. Search engines save their data alphabetically, just like a book’s index. Owing to the enormous amount of information, a search engine’s listings are not browsable. They are searched by entering words (or a phrase) that specifies what you are looking for, and the results are presented as a list in descending order of relevance (which is an indication of the positional frequency of the search term/s). Internet Guides, on the other hand, are designed to be browsed and offer a much more structured and selective approach to information gathering.

Unfortunately, of the estimated ∼30B pages on the WWW, coverage by the various search engines varies widely.\(^1\) This situation is further complicated\(^2\) by the possible exclusion of major search engines (e.g. HotBot and Northern Light) from the multifile search engines (e.g. Dogpile), in certain circumstances.

In addition, the popularity of Internet searching also magnifies the “principle of least effort”, which is exemplified by the obviously uninformed proclamations about the unique benefits of searching the WWW. A recent article\(^3\) has exposed some obvious deficiencies of depending on WWW searches for research articles (e.g. only about 10% of what one could retrieve from CAS Online is found on the WWW.)

This is not to diminish the importance of many important web pages and Internet-accessible databases. The WWW is extremely useful for finding material (specialized databases, personal and company-related information, and conference proceedings, etc.) that is not indexed in traditional sources, such as CA, Analytical Abstracts, or the Web of Science.

In addition to searching the WWW, there are numerous news groups that offer an opportunity to connect with others sharing similar interests. Some groups related to analytical chemistry include sci.chem; sci.chem.electrochem.battery; sci.chem.analytical; and sci.chem.electrochem.\(^3\)

**REFERENCES**

### 11.1 Analytical Chemistry Guides

- **Links to Internet Sources for Analytical Chemistry** http://cheminfoinformatics.indiana.edu/cicc/cis/index.php/Link_to_Internet_Sources_for_Analytical
- Chemistry is an extensive listing covering Spectral & Crystallographic Sources; Structural Databases: Biological Molecules; Amino Acids, Peptides, and Proteins: Structural Databases; Nucleic Acids: Sequence and Structural Databases; Miscellaneous Sources for Analytical Chemistry; and Printed Sources for Analytical Chemistry Information

**Analytical Sciences Digital Library** http://www.asdl.org/ is an NSF-funded digital library responsible for collecting, cataloging, linking, and publishing peer-reviewed web-based materials on innovations in curricular development and supporting technical resources.

- **UMEA University: Analytical Chemistry Springboard** http://www.anachem.umu.se/jumpstation.html. This site provides a comprehensive list of analytical chemistry resources on the Internet, covering both descriptions of analytical techniques (e.g. chemical sensors, mass spectrometry, sample preparation) and information resources (departmental listings, meetings and short courses, software).

### 11.2 Internet Search Engines

- **DOGPILE** http://www.dogpile.com is a Metasearch engine that provides combined results from: Google, Yahoo! Search, Live Search, Ask.com, About, MIVA, LookSmart and more).
- **GS** http://scholar.google.com/schhp? tab=ws provides access to a broad range of disciplines and multiple formats from a variety of sources: peer-reviewed papers, theses, books, abstracts, and articles, from academic publishers, professional societies, preprint repositories, universities, and other scholarly organizations.

### 12 MISCELLANEOUS TIPS

1. There are two slightly different transliteration schemes used by the Library of Congress and scientific publishers. For example,
2. There are also variations in American and British (Commonwealth) spellings: fetus–foetus, aging–ageing.

3. Accent marks, umlauts and compound names have not been treated consistently by various publishers.

<table>
<thead>
<tr>
<th>Published as:</th>
<th>WoS(&lt;1998):</th>
</tr>
</thead>
<tbody>
<tr>
<td>Brown-Wensley</td>
<td>BrownWensley</td>
</tr>
<tr>
<td>Van der Waals</td>
<td>Vanderwaals</td>
</tr>
</tbody>
</table>

An author search in SciFinder/SciFinder Scholar provides a listing of alternative spellings of author’s last names.

4. Alphabetical arrangement also varies between library catalogs (word-by-word) and dictionaries (letter-by-letter).

<table>
<thead>
<tr>
<th>Library Catalogs</th>
<th>Dictionaries</th>
</tr>
</thead>
<tbody>
<tr>
<td>(word-by-word)</td>
<td>(letter-by-letter)</td>
</tr>
<tr>
<td>Chemic green</td>
<td>Chemically pure</td>
</tr>
<tr>
<td>Chemical warfare</td>
<td>Chemical warfare</td>
</tr>
<tr>
<td>Chemically pure</td>
<td>Chemic green</td>
</tr>
</tbody>
</table>

5. The CASSI has a unique letter-by-letter arrangement of the abbreviations (which are bold faced). This results in the following alphabetical listing.

<table>
<thead>
<tr>
<th>Z. Chem.</th>
<th>Zeitschrift fuer Chemie</th>
</tr>
</thead>
<tbody>
<tr>
<td>Zeiss</td>
<td>Zeiss Information</td>
</tr>
<tr>
<td>Zh. Obsch. Khim.</td>
<td>Zhurnal Obschei Kimii</td>
</tr>
<tr>
<td>Z. Kristallogr</td>
<td>Zeitschrift fuer Kristallographie</td>
</tr>
<tr>
<td>Zoon</td>
<td>Zoon</td>
</tr>
<tr>
<td>Z. Phys.</td>
<td>Zeitschrift fuer Physik</td>
</tr>
</tbody>
</table>

6. The CA Author Index (in print) is unique in that the alphabetical arrangement of the author’s forenames are by the initials and not the full forenames. This results in the following alphabetical order:

Brown, D.;
Brown, Douglas D.;
Brown, Dennis Judson;
Brown, D. Kyle;
Brown, David Ward.

</table>
A concise yet comprehensive review of the use of microwave-assisted techniques for sample preparation in analytical chemistry is presented. A historical review of the development of the field is followed by summaries of the most significant theoretical principles, available instrumentation and safety considerations. The major part of the review concerns recent applications of the techniques to the preparation of a wide range of sample types. These include environmental, soil, biological, clinical, food, pharmaceutical, mineral, ceramic and industrial samples. Examples of microwave-assisted drying and fusion of analytical samples are also given. Throughout, reference is made to the most important review articles. Where appropriate, original papers are summarized and cited.

1 INTRODUCTION

Over the past decade, manufacturing industry generally has come under increasing pressure on two main fronts – economic and environmental. On the economic front, increasing competition due largely to globalization has forced companies to improve quality, efficiency and productivity. At the same time, society has become increasingly concerned with environmental effects, leading to more stringent controls on emissions and effluents. These influences have in turn made efficient management more and more dependent on reliable chemical analysis at all stages of the manufacturing process. Analytical chemistry has never had a more important role to play and the signs are that this role will become even more crucial in the future. These pressures have favored the trend for analytical chemistry instrumentation to become more and more sophisticated. Improved instruments with the capability to detect ever-smaller quantities of more and more elements and compounds, more rapidly than before, are constantly being developed and usually incorporate powerful computational capabilities. However, many of these advanced techniques require extensive sample pretreatment. Yet 10 years ago, few innovations had been made to sample dissolution or pretreatment methods for a century or more. Thus sample preparation had become the slow step in the analytical process, providing the impetus for the development of fast and reliable alternative methods to those traditionally employed. The innovative techniques introduced to speed up sample pretreatment include supercritical fluid extraction (SFE), solid-phase extraction (SPE), solid-phase microextraction (SPME), the supported liquid membrane (SLM) technique for extraction, accelerated solvent extraction (ASE) and high-performance capillary electrophoresis (HPCE).

However, some of the most significant advances in this area have been based on the use of microwave radiation to accelerate the process of sample preparation.

This article will focus on these developments and is an attempt to identify the most significant advances described in the literature up to the middle of 1999, along with sufficient background information to provide an overall perspective of the potentials and limitations of microwave-assisted techniques.

The preparation of biological samples by wet ashing at atmospheric pressure was the first chemical decomposition process to exploit the microwave oven for analytical purposes. The first microwave-assisted high-pressure dissolutions were reported about a decade later. Conventional wet ashing dissolution techniques are very slow,
and involve heating samples in various acids or mixtures of acids in an oven or on a hot-plate for extended periods of time. Often the sample – acid mixture must be brought down to dryness, cooled and then reheated with more acid in order to ensure dissolution. Also, these techniques are susceptible to loss of volatile analytes and cross-contamination. Other problems often associated with conventional sample preparation techniques include tedium, danger due to the use of strong oxidizers, incomplete digestion and the need for large amounts of reagents, constant supervision and special fume hoods. For those samples containing intractable matrices such as refractory minerals, closed vessels such as steel-jacketed Teflon® polytetrafluoroethylene (PTFE) bombs or glass Carius tubes heated in a conventional oven have traditionally been used – again, lengthy heating times are required.

In 1975, Abu-Samra et al. reported the use of microwave ovens for the purpose of wet ashing biological samples prior to elemental analysis. These authors used a domestic microwave oven equipped with a spray fume scrubber to wet ash a range of biological samples. The only previously recorded laboratory uses of microwave ovens were for the drying of wet cake and paste in an inorganic chemical manufacturing plant and for the sintering of silica and alumina mixtures. The inspiration for pressure-dissolution studies came from a US Bureau of Mines report, which described how rapid dissolution of some mineral samples had been achieved by using a microwave oven to heat samples and an acid mixture contained in polycarbonate bottles. When this experiment was repeated, the method showed great potential, but the vessels proved unsuitable for more rigorous conditions. A great deal of effort went into the search for better reaction vessels – the vessels needed to be transparent to microwave radiation, chemically inert and resistant to acid attack, able to withstand high temperatures and pressures and yet be reasonably cheap. Vessels should also be small enough to allow up to a dozen inside the oven at the same time, yet be readily sealed and opened to enable routine use by laboratory staff. A range of commercially available Teflon® bottles was tried, but these deformed or burst during the heating process. Some test vessels were machined out of solid Teflon® blocks, but it was found that the screw threads in the cap deformed during heating, allowing the cap to explode off. Finally, a vessel was constructed from 4-cm diameter Teflon®-PFA (polyfluoroalkoxy) tubing and end caps and this vessel was constructed from 4-cm diameter Teflon® during heating, allowing the cap to explode off. Finally, it was found that the screw threads in the cap deformed.

Dramatic reductions in sample preparation times, containment of volatiles and sample type versatility are evident advantages of closed vessel dissolutions over classical wet digestion methods. Closed vessels result in the development of high temperatures and pressures which make dissolutions much more vigorous and rapid, hence the greater speed of the technique. The increased acceptance of the microwave pressure-dissolution technique is reflected by the dramatic rise in the number of publications appearing over the past few years. These report dissolution methods involving geological, botanical, zoological, environmental, food, sludge, coal and ash, metallic materials and synthetic material samples. Other papers focus on drying, on-line/flow-injection/continuous-flow systems, extractions/desorptions, distillations, total nitrogen determinations (Kjeldahl), reviews, general reports and databases, automated/robotic systems, oven modifications, special dissolution techniques and equipment, safety and moisture content determinations. These topics are all discussed in some detail in the sections that follow.

In many analytical laboratories, the microwave pressure-dissolution technique is already the method of choice for sample preparation. The new protocols reported have been, in most instances, verified exhaustively against standard reference materials. Microwave pressure-dissolution must now be considered an accepted technique. Other microwave-assisted processes for sample preparation are being constantly developed, put into practice and gaining general acceptance. This is an extraordinarily dynamic and rapidly changing area of chemistry.

## 2 THEORETICAL CONSIDERATIONS

These have been covered in depth in a number of excellent reviews that of Mingos and Baghurst being particularly recommended.

### 2.1 Interactions of Microwaves with Matter

Microwaves form part of the spectrum of electromagnetic radiation, and fall below the infrared (IR) band, with frequencies of from 30 GHz to 300 MHz (corresponding to wavelengths of from 1 cm to 1 m). This is nonionizing radiation, with insufficient energy to rupture chemical bonds, but enough energy to cause molecular rotation.
or movement of ions. These effects will, in turn, cause heating. This region of the electromagnetic spectrum is also used for radio detection and ranging (RADAR) and telecommunications purposes. In order to cause as few disruptions as possible to these long-range uses, certain fixed frequencies have been identified by international agreement (International Radio Regulations, Geneva, 1959) for industrial, scientific and medical (ISM) use. The approved ISM frequencies are 13.56, 27.12, 40.68, 915 and 2450 MHz and 5.80 and 22.125 GHz.

Some materials (metals, for example) are completely impervious to microwaves, reflecting them and absorbing no radiation. Other materials are completely transparent to these waves, freely allowing their passage, again with no energy absorption. However, there are a whole range of substances which do absorb microwave radiation, and become heated as a result. The extent of the observed heating effect is dependent on a variety of factors.

Both conduction and dielectric polarization are sources of microwave heating. Dielectric polarization comprises several individual components, namely electronic polarization, atomic polarization, dipolar polarization and interfacial polarization (or the Maxwell–Wagner effect). With an oscillating electric field, such as that associated with electromagnetic radiation, the response of a material depends on the timescales of the orientation and disorientation phenomena relative to the frequency of the radiation. Since the timescales for electronic and atomic polarization/depolarization are much faster than the microwave frequencies, these two kinds of polarization can usually be ignored. In practice, only dipolar polarization and interfacial polarization make any significant contributions to the total polarization and hence to microwave heating because the timescales associated with them are comparable to microwave frequencies.

Polarizability may be represented by the dielectric constant ($\varepsilon'$). The greater the $\varepsilon'$ value, the more electromagnetic field energy can be stored in the material. Moreover, the dielectric loss ($\varepsilon''$) measures the efficiency with which the energy of the electromagnetic radiation can be converted into heat. It is known that $\varepsilon'$ and $\varepsilon''$ vary with frequency in different manners. Thus the (dielectric) loss tangent ($\varepsilon''/\varepsilon' = \tan \delta$) is defined to describe the ability of a material to convert electromagnetic energy into heat energy at a given frequency and temperature.

Dielectric relaxation occurs when the electric field that induces the polarization is removed. The time required to reduce the order to $1/e$ of its original value is referred to as the relaxation time ($\tau$). It can be calculated by the Debye equation$^{[30]}$ [Equation 1]:

$$\tau = \frac{\xi}{2kT} \quad (1)$$

where $\xi$ is a coefficient associated with the size of the molecule and its environmental effects. The theoretical calculation of $\varepsilon'$ and $\varepsilon''$ may be carried out by the use of the following Debye equations$^{[30,31]}$ [Equations 2 and 3]:

$$\varepsilon' = \varepsilon'_0 - \varepsilon'_\infty \frac{1}{1 + w^2 \tau^2} \quad (2)$$

$$\varepsilon'' = \frac{(\varepsilon'_0 - \varepsilon'_\infty) w \tau}{1 + w^2 \tau^2} \quad (3)$$

where $w$ is the frequency and $\varepsilon'_\infty$ and $\varepsilon'_0$ are referred to as the high-frequency ($w \gg 2\pi/\tau$) and static dielectric constants, respectively. The loss factor ($\varepsilon''$) has a maximum value when $w = 1/\pi$. Generally, because of the interaction of the molecules with their neighbors, the real relaxation spectra of liquids and solids do not coincide well with those predicted by the Debye equations. In these cases, a modification to the calculation of relaxation time ($\tau$) is necessary$^{[32]}$ [Equation 4]:

$$\tau = \tau_0 e^{U/kT} \quad (4)$$

where $\tau_0$ is a calculated relaxation time from the Debye equation and $U$ is the value of the potential barrier that a molecule has to cross when rotation occurs.

The dielectric constant of an inhomogeneous material, typically a suspension of conducting particles in a nonconducting medium, is also frequency dependent. Owing to the build-up of charges between the interfaces, dielectric loss is induced. This is known as the Maxwell–Wagner effect. The related absorption centred around a frequency of $10^7$ Hz may lie in the microwave region.

As one of the two sources of microwave heating, conduction loss can be viewed as an extended Maxwell–Wagner effect, which contributes to the total loss. This conductive part depends on the direct current (DC) conductivity itself. For highly conductive liquids and solids, conduction losses may be on the same scale as dipolar relaxation loss, and there comes a point where the conductive loss effects are larger than dipolar relaxation effects.

Finally, for microwave heating of liquids and solids, the rate of rise of temperature due to the microwave electric field is governed by Equation (5)$^{[33]}$

$$\frac{\delta T}{\delta t} = \frac{\text{constant} \times \varepsilon'' E^2}{\rho C_p} \quad (5)$$

where $E$ is the electric field intensity, $\rho$ the density of the material, $C_p$ the specific heat capacity and $f$ the frequency of the electromagnetic field in hertz. Since these physical properties and also the dielectric loss for liquid and solid samples, are all temperature dependent, carrying out a full theoretical analysis of dielectric heating is an extraordinarily complex task. Nevertheless, it is possible...
to make useful generalizations which assist in designing protocols for specific experiments.

In the case of liquids, polar compounds (e.g. water, ethanol) are readily heated in a microwave field, whereas nonpolar compounds (e.g. aliphatic or aromatic hydrocarbons) or those with molecules that have no net dipole moment (e.g. carbon tetrachloride) tend to be more transparent to microwave radiation and thus absorb very little energy and heat up far less readily. The electric field component of the microwave radiation interacts with the electric dipoles on the polar molecules leading to heating via dipole relaxation. For solutions containing dissolved ions, these can also interact with the oscillating electric field associated with microwave radiation, augmenting the dipole heating effect with a conduction effect.

Those solid materials that absorb microwave radiation efficiently (e.g. CuO and NiO) usually do so through a mechanism involving conduction by electrons, ions or holes. In addition, there may be microwave absorption by polar molecules weakly bound within the solid structure or lattice. For example, solid ice is transparent to microwave radiation, but heats rapidly owing to absorption by the liquid water molecules present within the structure. Other dipole interactions may be present in solids owing to irregularities in lattice structure and across grain boundaries.

The extent of the heating effect may also be frequency dependent. Hence the penetration of microwave radiation into water varies roughly with the wavelength of radiation used, so for deep penetration (to ensure the thorough cooking or warming of foods, for example) a longer wavelength (lower frequency) than that giving optimal absorption of microwave energy and leading to excessive surface heating is preferable. In practice, domestic microwave ovens operate at a frequency of 2.45 GHz, much lower than the 20 GHz that would give the optimal heating effect. Some restaurant models do have an additional and higher frequency (9.8 GHz) available for the browning of foods – the heating effect is augmented but confined to the surface region.

Hence the major mechanisms leading to microwave absorption and consequent heating in solid, liquid and gaseous materials are understood. However, the detailed mechanisms involved for any particular real-world system are complex and extremely difficult to model, since they include dipole moments, numbers and sizes of ions involved, concentration effects, temperature effects and frequency effects, in addition to changes in the microwave field which occur as the temperature and conditions within the substrate change.

2.2 The Magnetron and Instrument Components

The magnetron generates the microwave radiation. The external configuration of different magnetrons varies, but the basic internal structures are the same. These include the anode, the cathode or filament, the antenna and the magnets. The anode is a hollow cylinder of iron with an even number of cylindrical (or trapezoidal) cavities running on the inside parallel to the axis. The metal segments separating these cavities are called the anode vanes. When the magnetron is operating, the matched cavities behave as tuned circuits and determine the output frequency of the tube. Alternate segments must be connected, or strapped, so that each segment is opposite in polarity to the segment on either side. The cathode is a wire running through the center of the hollow anode, supported by the filament leads, which are carefully sealed into the tube and shielded. The antenna is a probe or loop that is connected to the anode and extends into one of the cavities. It is coupled to the waveguide, a hollow sheet metal conduit, into which it transmits the microwave radiation, which subsequently follows the waveguide into the oven cavity. Strong permanent magnets are mounted around the magnetron so that the magnetic field is parallel with the axis of the cathode.

Magnetron operation starts when a low voltage is applied to the wire cathode and, at the same time, a high potential is applied between the cathode and anode. Electrons stream off the heated cathode and are attracted strongly to the anode, but this motion is opposed by the magnetic field and so the electrons spiral around the cathode towards the anode. The whirling cloud of electrons, influenced by the high voltage and the strong magnetic field, forms a rotating pattern that interacts with the configuration of the interior surface of the anode to produce oscillating charges in the resonant cavities of the anode. The charge oscillation leads to the release of electromagnetic radiation at a specific frequency determined by the geometry of the cavities. Once the oscillations have increased sufficiently in amplitude, the radiation flows via the antenna into the waveguide and then into the oven cavity.

The cavity walls are metallic and reflect microwave radiation so that it may pass through the sample many times and yet be contained within the cavity. Oven doors are usually of transparent material covered with metallic gauze, which reflects the radiation. Particular care is taken with door design to ensure no radiation leakage. Standing waves within the cavity cause an uneven distribution of energy leading to “hot spots” – this problem may be reduced by the installation of a mode stirrer, which looks rather like a small ceiling fan. Alternatively, a rotating carousel on the floor of the oven, on which samples are placed, smooths out the field experienced by the target materials.

In a domestic microwave oven, the magnetron is either on, and operating at full power, or switched off. Hence the variable power settings available are made possible...
by pulsing the microwave power— that is, by alternately
switching the magnetron on and off according to a duty
cycle. Thus a 600-W oven with a 30-s duty cycle can
deliver an average of 300 W by switching the magnetron
on and off every 15 s. For chemical applications and the
minimization of oscillating temperature conditions in the
sample, very short pulse times are an advantage and
give greater control. Some specialized laboratory ovens
have programmable, continuously variable, unpulsed
microwave power sources.

For poorly absorbing samples, particularly where only
small quantities are available, it may be worth considering
an alternative to the multimode oven described above. A
single-mode resonant cavity may be tuned to the charac-
teristics of the particular sample. Such an experimental
setup has been described for use in the processing of
poorly absorbing polymers.\(^{35}\)

### 2.3 Microwave Heating and Superheating

During the early experiments involving microwave diges-
tion and synthesis, it was clearly understood that when
reactions were carried out in closed containers under high
pressures, solvent boiling points became elevated, allow-
ing the reaction mixtures to attain far higher temperatures
than would be present under atmospheric pressure, where
the normal boiling point of the solvent was the limiting
temperature. Thus accelerated reaction rates and dra-
matically reduced reaction times were readily explicable.
However, some observers noticed increases in reaction
rates or dissolution times when reactions were carried out
in open vessels under atmospheric pressure. This was one
of the reasons why the idea that there was some special
‘microwave effect’ in operation arose. This was of par-
ticular concern to the food industry, since it was feared
that microwave heating might lead to a different series of
reactions in foods subjected to microwave heating than
those heated in conventional ovens. It was also of great
interest to synthetic chemists seeking to alter the products
of various reactions. A simple series of experiments led
to some very significant results, which went a long way
towards explaining this particular anomaly.\(^{36}\)

The rapid heating associated with microwaves can lead to super-
heating in strongly absorbing solutions, e.g. water can
be heated to about 10 °C above its normal boiling point
under atmospheric pressure. An increase in temperature
of this order can lead to a two- or threefold increase in
reaction rate. Thus the more rapid dissolution of ana-
lytical samples in open vessels observed with microwave
heating\(^{(37,38)}\) may be explained without recourse to a spe-
cial effect. Repeated experiments have failed to confirm
that microwave heating is in any way different from con-
ventional heating in its chemical or physical effects on
matter.\(^{28}\)

### 3 INSTRUMENTATION AND EQUIPMENT

The intention of this section is to provide an overview of
the main types of instrumentation and equipment avail-
able commercially. Since this is such a rapidly expanding
field, the list given is not exhaustive. In most instances it
is possible to use relatively cheap domestic ovens to per-
form microwave-assisted chemical procedures. However,
the more expensive ovens specifically designed for labora-
tory operation have many desirable features which reduce
the risk of accidents permit a far higher degree of control
over the progress of the reaction taking place and allow
higher temperatures and pressures to be safely employed.

#### 3.1 Ovens and Complete Microwave Systems

A number of manufacturers now supply microwave ovens
specially designed for laboratory use. In general, these

</tbody>
</table>
are one or two orders of magnitude more expensive than domestic microwave ovens but have many features which make them safer and more effective for use in chemical analysis and research. Laboratory ovens have electronic components that are protected from the corrosive gases that will often occupy the oven cavity and are designed to eliminate the risk of sparking by switches, etc., which could ignite flammable vapors in the cavity. The overall construction is more robust and extensive use is made of stainless-steel components where appropriate. Ventilation from the cavity is often a feature. The elimination or reduction of hotspots in the cavity is usually one of the design targets – some instruments are fitted with rotating diffusers in the roof of the cavity, most make use of a carousel or rotating platform to house the sample vessels. Most ovens use a pulsed system in which power adjustment is controlled by switching the magnetron on and off successively, with the more advanced instruments having a shorter pulse time. Other instruments do have an unpulsed and variable source of microwave power. Some manufacturers sell the ovens as stand-alone instruments whereas others sell a complete microwave sample treatment system, including oven, vessels, and temperature and pressure monitors. Available accessories may include distillation equipment and facilities for handling open vessels where an efficient ventilation capability is essential. Some manufacturers either equip their ovens for carrying out Kjeldhal analyses, or may sell specialized ovens designed specifically for this purpose.

Computer control is available on most higher end instruments – this can include a library of stored protocols for a variety of sample types, full temperature and pressure predetermination with a printout of the whole experiment and even automatic sample and reagent dispensing.

One system now on the market (the QLAB 6000) enables users to carry out closed vessel, open vessel or discrete flow digestions all on the one instrument. In the discrete flow mode, each sample is pneumatically isolated and transported through a complete digestion cycle. The operator weighs and loads the samples and the instrument then completes the task – it adds reagents, agitates, transports the samples, digests, cools, rinses, dispenses, dilutes and cleans up ready for the next cycle, automatically. Other manufacturers will have similar systems available soon. A short review of this topic appeared recently. A summary of some of the ovens and oven systems currently available is presented in Table 1.

3.2 Vessels

Different vessels are used for high-pressure dissolutions or reactions and those carried out under atmospheric pressure. In addition, specialized vessels are available for fusions, distillations or Kjeldhal analyses.

Vessels used for high-pressure work are usually made with a high-purity Teflon™ or PFA liner and an outer jacket of a stronger microwave transparent material (e.g. ULTEM, made by GE). Some kind of pressure-relief valve or membrane is usually fitted. These vessels normally have a capacity of 150 mL and can withstand pressures up to 40 bar (600 psi). The temperature is limited by the 260 °C softening point of Teflon™. Some manufacturers claim that these vessels can withstand much higher pressures, but at the high temperatures generated, it is probably wise to adopt a conservative approach. Closed vessel digestion is ideal for those samples which are being dissolved in HNO₃ or HCl, since the boiling point of the acids is raised under the high-pressure conditions and the digestion reactions are speeded up. In a closed vessel digestion, there is no loss of volatile elements and no reagent loss, hence smaller reagent quantities are needed. However, for those digestions where H₂SO₄ is required, such as Kjeldahl or digestions of petroleum products, there is little advantage in using the regular closed vessel approach. This is because the boiling point of H₂SO₄ is 330 °C, way above the temperature available in a Teflon™-lined vessel. Consequently, a higher temperature and faster reaction time is attainable in a glass or quartz vessel with the reaction run at atmospheric pressure.

Very high operating temperatures and pressures (200 bar/350 °C or 2900 psi/350 °C) are available with the ultraCLAVE by Milestone. This has an unusual design in which the reaction vessels are completely contained inside a high-pressure enclosure.

4 SAFETY CONSIDERATIONS

The main hazards associated with the laboratory use of microwave-assisted techniques can be divided into two areas:

- accidental exposure to microwave radiation
- explosions/fires/chemical spills or leakages.

Exposure to microwave radiation in small doses is not necessarily dangerous – in fact, it has been used for many years in the treatment of a variety of medical conditions. The danger arises when the exposure is not detected. Human skin can readily detect heat radiation and if one accidentally comes into contact with a hot object, there is an automatic reaction to withdraw from the heat source. Any injury is immediately obvious and treatment may be applied. However, microwave radiation tends to penetrate the first layers of skin and tissue,
passing through them imperceptibly. The heating occurs at points deeper within the body or limb, in places where nerve ends are absent. Hence tissue can be heated to temperatures where serious damage may take place yet the victim remains unaware of the injuries that are being inflicted. In cases of high exposure, such injuries could lead to death, so avoidance of accidental exposure to microwave radiation is a crucial concern in all work associated with microwaves.

The dangers of chemical spills, fires and explosions are always present in the chemical laboratory when vigorous reactions take place, either by accident or design. So in principle, the risks involved in microwave-assisted chemical processes are not very different from those encountered in more traditional chemistry. The major difference is that fairly often, users are unfamiliar with the apparatus and protocols that they should be using in the microwave-assisted procedures which they are attempting. This can lead to the development of excessively high temperatures or pressures and the rupture or melting of reaction vessels, leading to accidents.

Microwave-assisted preparation of solid samples can occasionally cause electrical arcing inside the sample vessels when the sample is not submerged in the solvent. This carries the potential danger of igniting a flammable solvent and causing a fire.

Another significant safety aspect is the maintenance of the microwave unit itself. Since microwave-assisted pretreatment of samples often involves the use of strong acids or organic solvents, most laboratory microwave units exhaust poisonous gases from the sample cavity. This must be kept separate from the air that cools the circuitry, or it may lead to deterioration of the insulating materials leading to electronic failure. Such an occurrence has been reported and led to accidental exposure to high powered microwave radiation by an individual, when the safety power cut-off failed to function when the oven door was opened. Therefore, it is important not to store the entire microwave system under a fume hood, where corrosion of the electronics is almost certain to take place.

5 APPLICATIONS

5.1 Introduction and Review Articles

Microwave energy has a number of different applications in analytical chemistry:

- In electron spin resonance spectroscopy (ESR) [electron paramagnetic resonance spectroscopy (EPR)]. This technique, which has had a long history of development, uses microwave energy as the irradiation source and is widely used for structural analysis and in the elucidation of a variety of problems, particularly biochemical ones, involving species with unpaired electrons.

- In a microwave plasma (MP). These have been used as sources for atomic emission spectroscopy (AES) since the 1970s. Several common forms of this plasma source exist, including the microwave-induced plasma (MIP), the capacitatively coupled microwave plasma (CMP), the surface-wave or surfatron plasma, the microwave plasma torch (MPT), and some other unique designs. It is suggested that these MPs offer certain cost benefits in comparison with inductively coupled plasma (ICP) sources.

- In microwave-assisted sample preparation techniques such as microwave-assisted digestion (MAD), microwave-assisted extraction (MAE), microwave-assisted fusion, microwave-assisted derivatization and microwave drying. It is the applications of these sample preparation techniques that form the focus of this study.

A number of books, book chapters and review articles have appeared recently. These provide a general coverage of the topic. Their contents are summarized below.

- Microwave-enhanced Chemistry – Fundamentals, Sample Preparation and Applications. A wide-ranging survey of microwave-assisted chemistry. Sixteen chapters covering fundamental theory right through to applications in chemical synthesis and including sample preparation techniques.

- ‘SamplePrep Web: Analytical Sample-preparation and Microwave-chemistry Resource Center’. The authors have developed a web site [http://www.sampleprep.duq.edu/sampleprep], which is a resource for a wide range of protocols and ancillary information.

- ‘Standardization of Sample Preparation for Trace Element Determination Through Microwave-enhanced Chemistry’. The development of standard sample protocols using microwave digestion is discussed and a brief overview presented of some of the key steps in EPA method 3052. Advantages and disadvantages of the technique are outlined.

- ‘Microwave Digestion Procedures for Environmental Matrices’. A review of the applications of microwave energy to the digestion of environmental samples. Both open and closed microwave digestion methods are discussed. Trends in research are highlighted and universal digestion procedures for particular matrices identified.
• ‘Sample Preparation Using MAD or Extraction Techniques’.\(^{(46)}\) A review on microwave digestion or extraction as a sample preparation technique. Describes how the technique can be applied in both organic and inorganic determinations for various sample matrices.

• ‘Microwave Analysis Systems for Rapid Process Analysis’.\(^{(47)}\) The determination of moisture, solids, ash and fat contents are summarized and the speed of determinations using microwave systems is discussed, with particular reference to the CEM LabWave 9000 drying apparatus and the CEM MAS 7000 and AirWave 7000 microwave ovens. The replacement of wet ashing by microwave ashing for the determination of sulfate ash is recommended. Ashing times for a range of samples with a conventional and a microwave muffle oven are tabulated.

• ‘Microwave Processing of Ceramics’.\(^{(48)}\) This review is focused on the microwave processing of ceramics, which is fast emerging as a new field in material synthesis. Recent times have witnessed significant progress in the aspect of commercialization and application of the technology to new areas. The most significant developments have been the use of microwaves in the sintering of nonoxides, such as tungsten carbide-based components and powder metals, fabrication of transparent ceramics and the design of continuous microwave systems. While not covering analytical applications, this article will be of interest to those planning to use microwave fusion in sample preparation.

• ‘Microwave-assisted Sample Preparation in Analytical Chemistry’.\(^{(49)}\) A comprehensive review giving a broad overview of the topic and details of protocols used in the preparation of a wide variety of sample types.

5.2 Environmental Samples
This section is fairly broad and includes examples of treating soil samples and sewage sludge samples and related materials. There is some overlap between this and the next section, which deals with biological and clinical samples.

• ‘A Study of the Analytical Parameters Important for the Sequential Extraction Procedure Using Microwave Heating for Pb, Zn and Cu in Calcareous Soils’.\(^{(50)}\) This is a report of a four-step microwave extraction procedure for Pb, Zn and Cu fractionation for calcareous soils. For 1 g of soil with grain size < 50 μm, 20 mL of 1 M NaOAc at pH 5.0 was used for extraction of the fraction bound to the carbonate in the first step; 20 mL of 0.072 M NH₂OH · HCl in HOAc for the fraction bound to iron and manganese oxides in the second step; and HNO₃(0.02 M) + NH₄OAc (0.8 M) for the fraction bound to organic matter in the third step. Finally, the residue was dissolved with HClO₄ + HF, then diluted to 25 mL with HCl (1 M) for analysis of the residual fraction in the fourth step. Metals were determined by flame atomic absorption spectroscopy (FAAS). The validity of the method was verified by a mass balance using calcareous soils and two certified reference materials. The results obtained were appropriate for the assessment of the environmental risks.

• ‘Application of Microwave Extraction for Partitioning of Heavy Metals in Sewage Sludge’.\(^{(51)}\) Describes the application of microwave extraction for partitioning of heavy metals (Cu, Cr, Ni, Pb and Zn) in sewage sludge. The procedure used follows the four-stage Tessier sequential extraction method but with conventional heating replaced by microwave heating and elimination of the shaking operation. A significant time saving (more than 10 h) was obtained by this microwave-assisted Tessier extraction with comparable efficiencies to the conventional Tessier method.

• ‘Elemental Speciation and Coupled Techniques – Towards Faster and Reliable Analyses’.\(^{(52)}\) Procedures for simplifying and shortening sample preparation protocols in environmental speciation analysis are discussed. Advances in gas chromatography (GC) sample introduction for plasma source atomic spectrometry and sample preparation methods for multicapillary GC, including microwave-assisted solvent extraction (MASE) and microwave-assisted purge-and-trap techniques are considered. Examples given of the speciation of organometallic compounds in biological tissues and road dust by GC/MIP/AES and of cobalamins by high-performance liquid chromatography (HPLC)/inductively coupled plasma mass spectrometry (ICPMS). Integration of sample preparation and chromatographic separation into a single step is evaluated. The importance of multidimensional separation and detection techniques for the unambiguous determination of metallocompounds in biological species is discussed.

• ‘Microwave-assisted Distillation in Tritium Monitoring (in Japanese)’.\(^{(53)}\) Describes a simple microwave-heating distillation device for the rapid preparation of natural samples for environmental tritium (T) monitoring. The device consists of a hard-glass test-tube, an N₂-gas flow piping system, a cold trap and a microwave oscillator (2.45 GHz, 250 W max.). The T concentration in H₂O in pine needles was determined by distillation of a 13-g sample in the
test-tube at 90 °C (200 W) for 3 min under an N\textsubscript{2}-gas flow-rate of 3 L min\textsuperscript{-1}. The H\textsubscript{2}O was collected by a conventional low-background scintillation apparatus. T concentrations of the needles collected in the vicinity of an organic IR waste disposal facility were 5.0 Bq L\textsuperscript{-1} before burning and 7.9 Bq L\textsuperscript{-1} after burning operation.

- ‘Continuous Microwave Assisted Pervaporation/ Atomic Fluorescence Detection: an Approach for Speciation in Solid Samples’.\textsuperscript{54} This report describes a method for the speciation of mercury in solid samples. It is based on microwave-assisted pervaporation with atomic fluorescence detection in a continuous flow system. The sample was placed in a laboratory-made cell, and either SnCl\textsubscript{2} [for Hg(NO\textsubscript{3})\textsubscript{2}] or an oxidizing solution followed by SnCl\textsubscript{2} (for PhHgOAc) were injected into the sample via a syringe. The cell was then placed inside a microwave device so that the microwaves were focused only on the sample chamber. After application of the microwaves, the flow of gas or liquid in the upper acceptor chamber was started, and the Hg driven to the detector via a gas–liquid separator. Acceptable results were obtained for the speciation of mercury in a certified reference material.

- ‘Stability of Organic Pollutants During MAE from Solid Matrices’.\textsuperscript{55} Dry and wet soil samples (5 g) were dispersed in solvent (30 mL) and exposed to MASE at 100% power for 5 or 20 min at 50 or 145 °C. The solvents were hexane–acetone (1 : 1), methylene chloride–acetone (1 : 1), toluene–methanol (10 : 1) and methyl tert-butyl ether. The samples were spiked with a solution containing 95 semi-volatile organic compounds (VOCs) including neutral (34), polycyclic aromatic hydrocarbon (PAH) (22), basic (19) and phenolic (19) compounds and benzoic acid, prior to extraction. The extracts were concentrated under N\textsubscript{2} and analyzed by gas chromatography/mass spectrometry (GC/MS). Recoveries and correction for losses during concentration were obtained by comparing the results with those for extracts of spiked samples not subjected to MASE. Mean recoveries and 95% confidence intervals are reported. Hexane–acetone gave recoveries of >80% except for basic compounds and benzoic acid in dry soil. An extraction time of 20 min did not significantly increase recoveries, and an extraction temperature of 145 °C decreased the recoveries of basic compounds. Recoveries of basic compounds, benzoic acid and some phenolic compounds were higher for wet soil than dry.

- ‘Open Focused-microwave-assisted Sample Preparation Procedures: Fundamentals and Application to the Speciation of Tin and Mercury in Environmental Samples’.\textsuperscript{56} An attempt was made to investigate some of the fundamental principles underlying microwave digestion by measuring the permittivity changes of solutions during digestion. The experiments revealed a decrease in permittivity with increasing microwave heating time. The microwave-assisted leaching of organotin compounds and Hg species from sediments and the microwave-assisted solubilization of organotin compounds and Hg species from biological materials were also studied. Results of work recently carried out by the authors are compared with those obtained using extraction/determination procedures reported in the literature since 1989. The development and potential applications of open microwave sample preparation procedures are also discussed.

- ‘Analysis of Trace Elements in Coal Fly Ash and Their Leachates: Results of the ENEL–EDF Round-robin Test’.\textsuperscript{57} Eight Italian laboratories and four French laboratories participated in a round-robin test of the determination of trace elements (As, Cd, Cr, Cu, Hg, Ni, Pb, Sb, Se, V and Zn) in coal fly ash and its leachates. The analysis procedure consisted of MAD of fly ash samples, followed by FAAS, electrothermal atomic absorption spectroscopy (ETAAS) or inductively coupled plasma atomic emission spectroscopy (ICP- AES) of the digests. Acetic acid and water leachates of fly ash were also analyzed. The accuracy and precision of the results were acceptable, except for Hg and Sb. The greatest source of variability in the fly ash analysis was the digestion step, because of the possibility of incomplete digestion of the matrix. For the leaching tests, the greatest source of variability was the pH of the leaching solution, as the metals’ solubilities varied with pH, and therefore variations in pH could affect the final concentrations of the metals in the leaching solutions.

- ‘A Rapid Microwave-digestion Method for Colorimetric Measurement of Soil Organic Carbon’.\textsuperscript{58} Ground (<0.2 mm), air-dried and oven-dried soil (0.2 g) and 0.5-mL portions of standard solutions containing 0–10 mg of sucrose-C were treated with 5 mL each of 0.17 M K\textsubscript{2}Cr\textsubscript{2}O\textsubscript{7} and H\textsubscript{2}SO\textsubscript{4}, and the mixtures were heated in a microwave oven to an applied energy of 500 J mL\textsuperscript{-1}. The cooled mixtures were diluted to 30 mL with H\textsubscript{2}O, centrifuged at 5000 rpm for 5 min and the absorbances measured at 590 nm. The recovery of organic C relative to the result obtained by the dry-combustion method with use of a LECO analyzer was 91.7%. The proposed method is more rapid and precise, involves the use of smaller volumes of reagents and results
in less waste than the conventional wet-digestion method.
- "Voltammetric Procedure for Determination of Mercury in Soil Wastes After Wet Microwave Digestion".\(^{(59)}\) Describes how the determination of mercury in solutions after microwave digestion of solid waste sample can be performed by using differential pulse anodic stripping voltammetry (DPASV) in a flow-through system with a gold disk as the working electrode.

- "Automatic Flow-injection System for the Determination of Heavy Metals in Sewage Sludge by Microwave Digestion and Detection by Inductively Coupled Plasma Atomic Emission Spectroscopy (MW–ICPAES)".\(^{(60)}\) Results from the optimization of an automatic flow injection system combining MAD with atomic spectrometric detection (FAAS, ICPAES) to determine heavy metals in sewage sludge are presented. Digestion was performed by preparing a suspension of the sample in 1.5 M HNO\(_3\) and making it flow through a PTFE capillary tube placed inside a conventional microwave oven. The effects of capillary tube length and inner diameter and pumping rate were studied to establish the experimental conditions that allow a quantitative elemental recovery in the shortest possible time. The elements determined were Zn, Cu, Pb, Cd, Ni, and Cr. The optimized procedure was applied to one ordinary and one certified sewage sludge sample. In comparison with conventional methods of sewage sludge analysis, the proposed method was less time consuming and equally precise and accurate.

- "Microwave-assisted Pre-treatment of Environmental Samples for the Determination of \(^{90}\)Sr".\(^{(61)}\) In this paper, microwave-assisted pretreatment of environmental samples for the determination of \(^{90}\)Sr are presented. Six matrices were studied: organic and mineral soils, sediment, grass and ashes from grass. Total attack (using HNO\(_3\), HClO\(_4\), HF and H\(_2\)O\(_2\)) and leaching digestion methods, which avoided the use of HF, were optimized for each matrix. Since no statistically significant differences were found between the results obtained using the two procedures, leaching digestion was preferred, as long as the digestion time and the number and amount of reagent were lower. The influence of sample type on \(^{90}\)Sr activity concentration determination was studied and no significant influence was observed.

- \(^{210}\)Po and \(^{210}\)Pb Analysis in Sediments and Soils by Microwave Acid Digestion".\(^{(62)}\) A microwave acid digestion method prior to the determination of \(^{210}\)Pb and \(^{210}\)Po in sediments and soils is described. It involves an acid (HNO\(_3\), HCl, HF and H\(_2\)BO\(_3\) mixture) digestion with microwave heating in closed vessels at high pressures. Analyses carried out for various reference materials showed that the results were statistically the same as the certified values and the precision was good. The advantage of the microwave technique compared with the traditional leaching procedures is that the solid materials are completely dissolved and, therefore, almost 100% efficiency is achieved in the extraction of \(^{210}\)Po and \(^{210}\)Pb, even though a fraction is tightly bound to the silica matrix. Moreover, the time of analysis is drastically reduced, as are the risks associated with vapor inhalation and material corrosion.

- "An Optimized Microwave Digestion Procedure for Cadmium Analysis of Mussel Samples".\(^{(63)}\) Mussel (0.2 g dried sample) was treated with concentrated HNO\(_3\) in a closed vessel by microwave heating. After cooling, the resulting solution was adjusted to pH 5 with NH\(_3\) and concentrated on-line with a chelating resin. The cadmium was determined by AAS (atomic absorption spectroscopy). The analytical results agreed well with certified values for a mussel standard reference material.

- "Microwave-assisted Soil and Waste Dissolution for Estimation of Total Phosphorus".\(^{(64)}\) For the determination of P by ICPAES, the United States Environmental Protection Agency (USEPA) 3051(SW-486) microwave-digestion method was more effective and convenient, less labor intensive and safer than digestion with HNO\(_3\)–HClO\(_4\) in an aluminum block for the decomposition of soil, sediments, waste solids, sewage sludge and compost. The recovery and precision can be improved further for samples containing large amounts of organic matter by dry ashing before the microwave digestion. Recoveries of >93.5% were obtained.

- "Microwave Digestion for Analysis of Metals in Soil".\(^{(65)}\) The effects of H\(_2\)O\(_2\) addition to HNO\(_3\) for the microwave digestion of soil on the analyses of 10 heavy metals by ICP were investigated. For HNO\(_3\)-only digestion (method A), based on USEPA method 3051, organic soil (200 mg, or 500 mg for mineral soil) was digested with 10 mL of concentrated HNO\(_3\) in a closed vessel (heating at 180°C for 10 min, taking 20 min to reach 180°C). On cooling, the filtration, dilution and analytical procedures were followed. For method B, 2 mL of H\(_2\)O\(_2\) were added to the digestion vessel after the HNO\(_3\) digestion cycle and the microwave digestion repeated with the same program as for A, and with identical filtration, dilution and analytical procedures. The results showed that metal concentrations were greater in organic than mineral soils and addition of H\(_2\)O\(_2\)
to HNO₃ did not enhance metal recovery from soil compared with HNO₃ alone except in the case of Mn.

- ‘Sample Preparation for Trace Metals. Part II: Microwave Digestion’. Microwave digestion as a sample preparation tool for trace metal environmental analysis is discussed with a focus on contamination issues.

- ‘Comparison of Microwave-assisted Leaching Techniques for the Determination of Heavy Metals in Sediments, Soils, and Sludges’. Microwave-assisted USEPA method 3051 for the HNO₃ leaching of environmentally key elements from sediments, soils and sludges was tested, and the influence of leaching temperature and time on element recovery for an estuarine sediment was investigated. The leaching efficiencies for four certified reference materials applying USEPA method 3051, an optimized HNO₃ procedure and an aqua regia [HCl–HNO₃ (3:1)] procedure were compared. Digestions were carried out in a high-pressure microwave system offering simultaneous temperature and pressure control for all digestion vessels employed. Eight elements (Cd, Co, Cr, Cu, Hg, Ni, Pb and Zn) were determined by ICP-MS. The extraction efficiency strongly depended on the applied leaching parameters and varied for certain elements among different materials when an HNO₃ procedure was applied. In general, element recoveries obtained from the aqua regia procedure were superior to those obtained from HNO₃ procedures and showed good agreement (95% confidence interval) with the certified value for most of the elements investigated.

- ‘Use of Microwave Digestion for Estimation of Heavy Metal Content of Soils in a Geochemical Survey’. Soil (0.5 g) was microwave digested for 30 min in a mixture of 10 mL of H₂O, 5 mL of HNO₃, 4 mL of HF and 1 mL of HCl, and the resultant digest was treated with 2 g of boric acid to complex excess fluoride as tetrafluoroborate. Cu, Ni, Zn, Cd, Cr and Pb were determined with FAAS or ETAAS.

- ‘Microwave Digestion of Ancient Peat and Determination of Pb by Voltammetry’. Different acid compositions (HNO₃, H₂O₂, HF and HClO₃) and low-pressure microwave digestion were applied to the microwave-assisted dissolution of ancient peats. The digests were evaluated with respect to the decomposition of the inorganic and organic fraction of the peats and to an optimized determination of Pb by DPASV. Addition of HF was necessary to achieve a complete dissolution of the resistant inorganic phase of the peat and to obtain total Pb recovery. Addition of HClO₃ decreased the concentration of dissolved organic C significantly, allowing reliable voltammetric signals for Pb determinations with appropriate peak shape, baseline, sensitivity and precision.

- ‘Optimization of the Reduction of Selenium(VI) to Selenium(IV) in a Microwave Oven’. Water samples were made 10 mM in HCl and agitated ultrasonically to remove CO₂. Portions were analyzed directly to determine Se(IV). Further portions (25 mL) were transferred to PTFE vessels, made 4 mM in HCl and the vessels were capped and heated in a microwave oven at 600 W for 3 min, giving 100% reduction of Se(VI) to Se(IV). The total Se(IV) was then determined. The samples were pumped at 7 mL min⁻¹ and mixed with 1% NaBH₄ in 1% NaOH and with 8 M HCl (both at 1 mL min⁻¹). The H₂Se was determined by AAS. Selenomethionine and selenocystine gave partial and variable yields of H₂Se under these conditions and needed to be separated, e.g. by cation-exchange treatment. The method was applied to the analysis of six samples of mineral water, for which the prior removal of high CO₂ concentrations, as described, was essential.

- ‘Levels of Organochlorines in Penguin and Skua Eggs from the Antarctic Determination after Application of Focused Open-vessel MAE in Combination with Gel Permeation Chromatography (GPC)’. Organochlorines in penguin and skua eggs from the Antarctic were determined after application of focused open-vessel MAE in combination with GPC. Extraction of the entire, partly lyophilized eggs was performed with ethyl acetate–cyclohexane. It was shown to be an excellent method for the quantitative determination of organochlorines in the parts per billion to trillion range because it allows the use of large quantities of sample.

- ‘Combined MAE and GPC for the Determination of Chlorinated Hydrocarbons in Seal Blubber and Cod Livers’. A fast and effective sample clean-up procedure for the quantification of chlorinated hydrocarbons in seal blubber and cod livers is reported. Lipophilic sample ingredients were extracted by application of microwave energy. MAE was performed with ethyl acetate–cyclohexane as solvent. Without exchange of the solvent, the organochlorine compounds were separated from matrix co-extractives by GPC. Traces of matrix remaining were separated from deactivated silica prior to gas chromatography/electron capture detection (GC/ECD). The polychlorinated biphenyl (PCB) compounds 153, PCB 138 and PCB 180, hexachlorobenzene (HCB) and p,p’-dichloro-di(chlorophenyl)ethylene were targets for quantification. In seal blubber, the recovery rates for these organochlorines were >90% following the complete sample clean-up procedure. MAE of cod
livers required milder conditions. After optimization of the MAE conditions, the organochlorine levels in cod livers were almost identical with those determined with other independent clean-up methods.

- ‘Fast Extraction of Dioxins from Fly Ash. Comparison of Soxhlet, SFE and Microwave-assisted Soxhlet Extraction’\(^\text{(73)}\), MASE was tested for the extraction of dioxins from waste incinerator fly ash, for which SFE is sometimes not effective. SFE can be considered as an alternative to Soxhlet extraction for low C-level fly ash, but when the percentage of C is high (about 15%), MASE may be preferable.

- ‘Extraction of Hexaconazole from Weathered Soils: a Comparison Between Soxhlet Extraction, MAE, SFE and ASE’\(^\text{(74)}\). Extraction of hexaconazole residues, weathered over periods of time varying between 0 and 52 weeks, was undertaken from two characterized soils. The various extraction techniques considered were Soxhlet extraction, MAE, SFE and ASE. In this case, the best precision was obtained for the automated ASE system.

- ‘Pesticide Analysis without Sample Transfer’\(^\text{(75)}\). Problems in Soxhlet extraction are discussed, and the advantages of microwave extraction outlined, e.g. extraction of 12 samples takes only 60 min including sample preparation and samples from a few milligrams up to 500 g can be handled. The easy WAVE software for controlling the heating program and the filtEX glass filtration and drying unit are briefly described. For the extraction of 2,4,6-trichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid and 2-(2,4,5-trichlorophenoxy)propionic acid from soil, a 2-g sample was extracted with 10 mL of methanol at 120 °C and 300 W for 15 min in a filtEX unit, which allowed subsequent filtration and concentration of the extract without transfer before analysis by HPLC. The determination of hexachlorocyclohexane and other polychlorinated compounds was carried out by GC/ECD after extraction in a filtEX unit.

- ‘Extraction of Organic Substances with Solvents’\(^\text{(76)}\). MAE was carried out under pressure in an MLS-ETHOS apparatus equipped with Teflon™ vessels, which allowed nonpolar solvents to be heated by microwaves. The vessels contained magnetic stirring bars and were purged with an inert gas. The system was used for the extraction of 5-g soil samples with hexane–acetone (1 : 1); up to 12 sample holders could be accommodated in the pressurized rotor and extraction at 500 W and 115 °C with stirring took 10 min. The extracts could be concentrated by evaporation without transfer. Reproducibility was better and extraction was 20–30% faster with stirred than with unstirred samples. Recoveries of, e.g. acetophenone, aniline derivatives, phenol derivatives and lindane by microwave (with and without stirring), Soxhlet and ultrasonic extraction are tabulated.

- ‘Microwave vs. Soxhlet for the Extraction of PCDD (polychlorinated dibenzo-p-dioxin) and PCDF (polychlorinated dibenzofuran) from Sewage Sludge Samples’\(^\text{(77)}\). Dried, ground, sewage sludge (10 g) was added to 0.3 g of H₂O and equilibrated for 10 min. A standard solution containing 15 \(^{13}\)C-labeled 2,3,7,8-substituted isomers of PCDD and PCDF was added, followed by 30 mL of toluene. Microwave extraction was carried out at 15, 20, 25 and 30% using a Soxwave 100 (Prolabo). Soxhlet extraction was carried out for comparison, for 48 h with 300 mL of toluene in the presence of 5 g of copper to remove sulfur interferences. Quantitative determination was carried out by isotope dilution. Recoveries ranged from 30 to 70% for the 15 analytes and two recovery standards. The advantages of MAE include reduced extraction time and reduced solvent use. The method is proposed as a viable alternative to Soxhlet extraction.

- ‘Focused MAE (FMAE) of Polynuclear Aromatic Hydrocarbons from Contaminated Soil: Role of Acetone and Water Content Impact on Microwave Efficiency’\(^\text{(78)}\). Portions (5 g) of dried soil were mixed with 1-mL aliquots of H₂O, transferred to a quartz container and microwave extracted with 40 mL of CH₂Cl₂–acetone (1 : 1) at 30 W for 10 min. The recovery of 15 PAHs (0.07–2.3 ppm), in comparison with 8-h extraction with 220 mL of anhydrous CH₂Cl₂ in a Soxhlet apparatus, took as 100%, was 70.8–128.1% (lowest for naphthalene) and the RSDs were 9.6–17.2% (mean 13.1%) compared with 8.1–36% (mean 22.7%) for the Soxhlet method (n = 5).

- ‘A Comparative Study of MAE and Soxhlet Extraction for Phenols in Soil Samples Using an Experimental Design’\(^\text{(79)}\). A comparative study of MAE and Soxhlet extraction for the separation of five phenols from soil is reported. Factorial and central composite designs together with the simplex method were used to optimize the extraction conditions for both techniques. For phenol, 2-chlorophenol and 2,4-dichlorophenol, comparable recoveries were obtained by both methods. For 2-ethylphenol and 2-nitrophenol, MAE gave better recoveries than Soxhlet extraction. The RSDs were 7.5–31% and 2.5–30% for MAE and Soxhlet extraction, respectively.

- ‘The Evaluation of Rapid Solid Sample Extraction Using the Microwave-assisted Process (MAP) under Closed-vessel Conditions’\(^\text{(80)}\). Samples of soil or
abbreviated microwave extraction of pesticides and PCBs in soil. Samples of soil material were microwave extracted with 8 mL of hexane–acetone (1:1) in a closed vessel. The microwave oven was operated at full power and samples maintained at 115°C for 15 min. After cooling, the extracts were analysed by GC/ECD. Recoveries of pesticides and PCBs were comparable to those obtained by Soxhlet extraction. A method for the chemical analysis of volatile constituents of the exhaled air of mechanically ventilated patients is described. Exhaled substances were adsorbed and concentrated on to activated charcoal, desorbed by microwave energy and transferred into a gas chromatograph for separation without prior cryofocusing. Substances were identified by flame ionization detection and mass spectrometry. This method gave reproducible results and appears well suited for clinical studies.

5.3 Biological and Clinical Samples

There is some overlap between this and the previous section, since biological samples are often analyzed to assess environmental pollution levels, and some clinical samples are used for monitoring exposure to environmental pollutants.

- 'A Method for Analysis of Exhaled Air by Microwave Energy Desorption Coupled with GC–Flame Ionization Detection–Mass Spectrometry'. A method for the chemical analysis of volatile constituents of the exhaled air of mechanically ventilated patients is described. Exhaled substances were adsorbed and concentrated on to activated charcoal, desorbed by microwave energy and transferred into a gas chromatograph for separation without prior cryofocusing. Substances were identified by flame ionization detection and mass spectrometry. This method gave reproducible results and appears well suited for clinical studies.

- 'Microwave-assisted Vapour-phase Nitric Acid Digestion of Small Biological Samples for ICP Spectrometry'. The sample digestion container developed earlier for use with a commercially available high-temperature–high-pressure asher was modified to fit into the digestion vessel of either a PMD, QWave 3000 or a Floyd-RMS150 microwave decomposition system. The modified container was constructed from quartz, and had an effective volume of 1.8 mL. Typically 50–100 mg of powdered sample were placed in the container and this was moistened with 250 μL of H₂O. Then the container was placed in the microwave digestion vessel containing 2 mL (for the PMD) or 10 mL (for other microwave digestion system) of sub-boiling HNO₃, and digestion was carried out at 450 W and 1200 psi, 75 W and
focused microwave system prior to ICPMS was digested at 50–60 W power for 3 min with 5 mL of aqueous 25% tetramethylammonium hydroxide. The solution was diluted to 15 mL with H2O, adjusted to pH 5 with acetic acid and extracted with 1 mL of 2% NaBEt₄ and 1 mL of nonane for 5 min. The organic phase was separated and analyzed for tin species as described. The 1S procedure was applied to the analysis of mussel and sea urchin eggs.

- 'The Importance of Vessel Materials for Ultra-trace Analysis (Part 2)'. Gallstones were subjected to microwave digestion at 220°C and ≤80 bar in HNO₃ (1:1)–30% H₂O₂ (2:1) in a vessel with a Hostafon TFM PTFE liner. Waste water and soil were decomposed similarly in 65% HNO₃ at 170°C and ≤8 bar and 180°C and ≤4.5 bar, respectively, in a vessel with a polyfluoroalkoxy (PFA) liner. Raster electron microscopy shows that the PFA surfaces were virtually unaltered after 100 digestion cycles whereas the Hostafon TFM surface was damaged and made porous after 45 digestion cycles. Hence PFA but not Hostafon TFM liners should be used in the microwave digestion of samples before ultratrace analysis.

- 'Voltammetric Analysis of Biological Samples and Soil After Wet Digestion Using Microwave Irradiation'. The use of low-pressure CEM vessels for determining Cd, Pb, Cu and Zn in trees and soil by DPASV and testing the effectiveness of mineralization for determining the Al content in trees by absorptive cathodic voltammetry using Alizarin S as complexing agent are described.

- 'Microwave-accelerated Sample Preparation for Speciation Analysis of Organotin Compounds in Biomaterials'. One-stage (1S) and two-stage (2S) procedures are described for the preparation of biological materials for speciation analysis of organotin compounds by GC. For the 1S procedure, 0.1–0.2 g of lyophilized tissue (1–2 g of wet tissue) was microwave digested at 40 W power for 3 min at a temperature of 130°C with 5 mL of acetic acid, 1 mL of nonane and 3 mL of 2% sodium tetraethylborate (NaBEt₄). The organic supernatant was analysed by gas chromatography/atomic emission spectroscopy (GC/AES) or gas chromatography/flame photometric detection (GC/FPD) after purification on alumina with diethyl ether as eluent. For the 2S procedure, 0.1–0.2 g of lyophilized tissue was microwave digested at 50–60 W power for 3 min with 5 mL of aqueous 25% tetramethylammonium hydroxide. The solution was diluted to 15 mL with H₂O, adjusted to pH 5 with acetic acid and extracted with 1 mL of 2% NaBEt₄ and 1 mL of nonane for 5 min. The organic phase was separated and analyzed for tin species as described. The 1S procedure was applied to the analysis of mussel and sea urchin eggs.

- 'Determination of Aluminium in Serum by Electrothermal Atomic Absorption Spectrometry with Prior Sample Pretreatment by Microwave Digestion and SPE'. Serum (0.5 mL) was mixed with 0.5 mL of concentrated HNO₃ and 0.2 mL of concentrated HClO₄ (both purified by sub-boiling distillation) in 7-mL PTFE/PFA phials. Three of the sealed phials were mounted on top of each other in twelve 120-mL digestion vessels and the 36 phials were simultaneously subjected to microwave digestion. The solutions were evaporated under an IR lamp. The residues were dissolved in 1 mL of 0.1 M HCl, treated with 0.1 mL of 1% 8-quinolinol in dilute HCl and adjusted to pH 9 with ammonia. Each solution was applied to a short column of 0.5 g of XAD-4 resin (20–50 mesh), the resin bed was washed with 5 mL of H₂O and the Al(III) was eluted with 1 mL of 0.1 M HCl at 0.25 mL min⁻¹. The eluates were analyzed by graphite furnace AAS.

- 'Focused MAD of Biological Reference Materials for the Determination of Trace Metals by ICPMS'. A rapid method for the preparation of biological materials based on their digestion in a low-power focused microwave system prior to ICPMS was developed. The samples were decomposed using a three-step attack with 30% nitric acid at (a) 30 W for 5 min, (b) 50 W for 6 min and (c) 80 W for 6 min. This was followed by cooling the mixture and subsequently reacting it with a 15% solution of hydrogen peroxide at 30 W for 5 min. The resultant solution was diluted with 2% nitric acid and aspirated to the nebulizer. Eight elements (Mg, Mn, Ni, Cu, Zn, As, Sr and Cd) were determined simultaneously using the peak hopping mode and external calibration of the ICPMS system. The method was validated by the analysis of four reference materials.

- 'Low Volume Microwave Digestion for the Determination of Selenium in Marine Biological Tissue by Graphite Furnace AAS'. An MAD procedure for determining Se in marine biological tissues was developed using three certified reference materials containing 1.62–6.88 μg g⁻¹ Se as model samples. Quantitative recoveries were obtained with a power/time microwave digestion program consisting of 600 W for 2 min, 0 W for 2 min and 450 W
for 45 min. The digestions were performed in sealed PTFE vials (7-mL capacity) loaded with 0.025–0.1 g of freeze dried tissue and 1 mL of HNO₃. Recovery tests were carried out by spiking oyster, dogfish and lobster samples with six species of selenium (selenite, selenate, selenomethionine, selenocysteine, selenocystamine and trimethylselenonium). These gave quantitative recoveries (94–105%) for all the species apart from trimethylselenonium (90–101%).

- ‘Microwave Radiation as a Factor Intensifying Sample Preparation: Analysis of Samples with an Organic Matrix’. The necessity of using a controlled-pressure microwave system (e.g. the MDS-81D, CEM) for the safe and rapid decomposition of organic matrices with the simplest reagent mixtures is emphasized. Conditions were established for the decomposition of vegetable materials (leaves, grass, cereals and foods), vegetable oils, cosmetics (shampoo, cosmetic milk and cream, lipstick and hair gel) and biological fluids (blood and serum) for the determination of trace elements by AAS and ICPAES.

- ‘Online Microwave Slurry Sample Digestion Using Flow Systems for the Spectrophotometric Determination of Iron in Seafood’. Lyophilized, powdered samples (250 mg) were ultrasonicated with HNO₃–H₂O₂ (oyster) or aqua regia–H₂O₂ (mussel, fish). A portion (200 µL) of the resulting slurry was injected into a flow system and carried by an air flow (8 mL min⁻¹) to a 2-m PTFE coil for microwave irradiation at 700 W for 10–20 min. After digestion, the slurry was eluted from the flow system with 14 mM HNO₃ (oyster) or 0.15 M HNO₃–0.35 M HCl (mussel, fish) and collected in a final volume of 10 mL (5 mL for fish). A portion (200 µL for oyster and fish; 130 µL for mussel) of the resulting solution was injected into a carrier stream (2 mL min⁻¹) of 14 mM HNO₃ (oyster) or 0.15 M HNO₃–0.35 M HCl (mussel, fish) and mixed successively with streams (all 1 mL min⁻¹) of 1% ascorbic acid, 0.25% 1,10-phenanthroline and acetate buffer to give a final pH of 3.7. Finally, the absorbance was measured at 512 nm.

- ‘The Optimization of Microwave Digestion for Determination of Selenium in Human Urine by Flow Injection-Hydride Generation–Atomic Absorption Spectrometry’. A microwave digestion program designed to decompose and oxidize completely selenium compounds in urine to selenite is reported. This involves monitoring the pressure and the temperature during microwave digestion. The complete decomposition and quantitative recovery of trimethylselenonium iodide spiked into urine was achieved in 18 min using an optimized microwave program reaching 200°C and 8 bar. The selenite in the digest was reduced to selenite by hydrochloric acid with the aid of microwave energy. Selenomethionine and selenoethionine were found to be unstable during the microwave heating used to reduce selenite to selenite. It is suggested that such a microwave reduction procedure could be used to distinguish selenate from selenite in those matrices which might contain organic selenium compounds.

- ‘Spectrophotometric Determination of Pb in Urine with Microwave Digestion and a Dithizone–Water Phase’. A method for the spectrophotometric determination of Pb in urine with microwave digestion and a dithizone–H₂O₂ phase is described. A complex is formed by Pb²⁺ and dithizone in the pH 8.5–9.0 H₂O₂ phase with Tween-20 as solubilizing agent.

- ‘Determination of Five Selenium Compounds in Urine by Liquid Chromatography with Focused MAD and Hydride Generation–Atomic Absorption Spectrometric Detection’. A method is proposed for the determination of trimethylselenonium ion, selenomethionine, selenocysteine, selenite and selenate in urine, following purification with C₁₈ cartridges. The on-line system consists of an anion-exchange chromatographic column for species separation, a focused microwave oven for the oxidation of organic Se species in the presence of 3% K₂S₂O₃ and 3% NaOH solution and reduction of selenite to selenite in 10 M HCl.

- ‘Determination of Mercury Species in Fish Reference Materials by Isothermal Multicapillary GC with Atomic Emission Detection after Microwave-assisted Solubilization and MASE’. Samples of freeze-dried tissue (0.1–0.2 g) were mixed with tetramethylammonium hydroxide (5 mL) and exposed to a 45-W microwave field for 2.5 min. After digestion, the samples were diluted with H₂O (15 mL) and the pH was adjusted to 4 with 1.5 mL of concentrated acetic acid (1.5 mL) and acetate buffer (5 mL). Sodium tetrathylborate (1 mL of 1%) and hexane (2 mL) were added and the mixture shaken. The extraction was repeated twice with fresh tetrathylborate (hexane not added), the sample centrifuged and an aliquot of the supernatant analyzed by GC. The method was validated by the use of certified reference materials.

- ‘The Molecular Stability of Genomic DNA of Phytoplasm in the Witches’-broom-affected Paulownia Tissues after Microwave Heat Treatment’. A comparative study was made on the use of microwave heat, air drying of tissue samples or fresh tissues from the midribs, petioles and tissue
cultures of paulownia that were infected or uninfected by phytoplasma prior to extraction of total genomic DNA. The DNAs extracted after these treatments were subjected to polymerase chain reaction (PCR) amplification using oligonucleotide primers targeting 16S rDNA, followed by restriction endonuclease treatments to establish restriction fragment length polymorphism (RFLP) profiles for comparison of treatment conditions and for comparison of witches'-broom-diseased tissues with normal paulownia tissues. DNAs extracted from microwave heat treated and from untreated phytoplasma showed identical nucleotide sequences, suggesting that the brief microwave heat treatment of 0.5 g of midribs and petioles for up to 14 min and 0.5-g tissue cultures for up to 20 min rendered phytoplasma noninfectious, but facilitated the preservation of phytoplasma DNA in situ without compromising the molecular stability. This simple method provides a means for long-term preservation and international exchange of phytoplasma specimens for molecular genetic studies between different laboratories.

- ‘Microwave Extraction of Aerial Parts of Zygophyllum Gaetulum’. (99) MAE of saponins from the aerial parts of Zygophyllum gaetulum was investigated. Samples were ground and mixed with an appropriate solvent [MeOH, EtOH, MeOH–H2O (8:2) and MeOH–H2O (1:1)]. Microwave irradiation was performed for 2 min. After cooling to room temperature, the irradiation was repeated several times. The MAE procedure proved to be better than Soxhlet extraction with regard to the time and effort employed.

- ‘A Rapid Microwave Method to Extract Plasmid DNA from Saccharomyces cerevisiae Suitable for the Transformation of Escherichia coli’. (100) A rapid microwave method to extract plasmid DNA from Saccharomyces cerevisiae suitable for the transformation of Escherichia coli is reported. The method was developed using different yeast strains and different microwave powers.

- ‘Optimization and Comparison of Two MAE Procedures of Terpenic Compounds in Vitis vinifera Must Samples’. (101) In the first experiment, a sample (150 mL) of Vitis vinifera must was shaken with 2.5 g of Amberlite XAD-2 resin for 15 min, the mixture was filtered and the residue was microwave extracted with 30 mL of acetone–dichloromethane (1:1) in a sealed vessel using a 950-W microwave oven operated at 50% of its maximum power level. The mixture was heated to 0.5 mL and analyzed by GC/MS (details given). In the control experiment, 6 mL of must were microwave extracted directly with 10 mL of dichloromethane at 100 °C for 10 min. The extract was then analyzed as described above. The calibration graphs were linear from 10 to 30 and from 1 to 16 mg L⁻¹ of terpenic compounds using the two extraction procedures, respectively. Recoveries were 88.7–94.9 and 80.1–86.8% for the two procedures, respectively. The methods were optimized by factorial design. Full details of the factor levels and extraction parameters used during the optimization processes are given.

- ‘Detection of Residues of the Epoxy Adhesive Component Bisphenol: a Diglycidyl Ether (BADGE) in Microwave Susceptors and its Migration into Food’. (102) Susceptors are an example of one of the many new products being introduced into food packaging. They are compounds which strongly absorb microwave radiation, creating very high temperatures on the surface of specific foods. This has the effect of browning the food during microwave cooking.

- ‘Determination of Major Minerals in Dairy Products Digested in Closed Vessels Using Microwave Heating’. (103) An improved digestion method for dairy products (cheeses, caseinates and milk powders) for subsequent determination of Ca, Mg, K and Na is described. Comminuted samples (100 mL) were digested with three acid mixtures: (a) 2 mL of HNO3 + 2 mL of H2O2, (b) 2 mL of HClO4 + 2 mL of H2O2 and (c) 2 mL of HClO4 + 1 mL of H2O2, in a microwave reactor for 5 min at 650 W and 10 min at 380 W. The reaction vessels were cooled in an ice bath.

- ‘A Streamlined Flame Atomic Absorption Method for Animal Feed Analysis’. (104) A faster digestion protocol using nitric acid and microwave digestion is reported for the preparation of animal feed samples. FAAS using on-line dilution and the automated addition of lanthanum solution provided a much easier and quicker analysis of the feed samples.

- ‘Accelerated Microwave Pre-treatment of Meat Samples Before Automated Determination of L-hydroxyproline’. (105) The method described is one in which 3 g of meat were microwave digested with 50 mL of 50% HCl solution in a closed vessel for 15 min at 800 W, or in an open vessel for 2 h at 200 W. The digest was neutralized with NaOH, diluted to 250 mL with water and a portion (100 µL) was analyzed by injection into an H2O carrier stream. This was merged with a stream containing chloramine-T, and then merged with a stream containing p-dimethylaminobenzaldehyde. The resulting
colored product was monitored at 560 nm. Both methods (open and closed vessel) gave results comparable to those obtained by digestion in a sand bath, but required only 2 h or 15 min, respectively, compared with the 8 h needed for sand bath digestion. The closed vessel method was the most efficient as it required the shortest digestion time, and because 12 samples could be treated simultaneously, compared with one sample at a time for the open-vessel method.

- ‘Use of a Microwave System for Polyphosphate Determination in Meat Products’\(^\text{(106)}\) Polyphosphate in meat was determined on the basis of the difference between total phosphorus (determined spectrophotometrically after microwave-based ashing) and organic phosphorus (estimated by using a conversion factor applied to the total protein determined by the Kjeldahl procedure). For total phosphorus determination, samples were digested in a microwave oven using nitric acid and hydrogen peroxide. Data obtained by using sausage and ham indicate that recoveries obtained after microwave digestion were higher than with traditional methods.

- ‘Microwave Mineralization of Confectionery Samples and Determination of Trace Quantities of Heavy Metal Ions in Mineralizates’\(^\text{(107)}\) A wet mineralization method using a microwave irradiation energy source was optimized for the decomposition of confectionery samples for analysis. HNO\(_3\) and H\(_2\)O\(_2\) were used as oxidizing reagents. Optimal reagent quantities, mineralization time and irradiation energy were determined. The amounts of selected heavy metals (Pb, Cu, Zn, As and Sn) were determined in various confectionery samples. It was shown that the microwave mineralization was very fast and suitable for analytical use.

- ‘Application of Atmospheric-pressure Microwave Digestion to Total Kjeldahl Nitrogen Determination in Pharmaceutical, Agricultural and Food Products’\(^\text{(108)}\) Samples (200 mg) were digested with H\(_2\)SO\(_4\) (20 mL) and 2 g of catalyst in a borosilicate reactor and then heated for 27 min in a microwave oven. Next, the mixture was cooled, treated with 33% H\(_2\)O\(_2\) (7 mL) and heated for a further 3 min. Total nitrogen was determined according to the conventional method, by distilling the reaction mixture after rendering it alkaline and titrating the distillate. The results were in good agreement with those obtained by the official classical method.

- ‘Determination of Dissolved Combined Amino Acids Using Microwave-assisted Hydrolysis and HPLC Precolumn Derivatization for Labeling of Primary and Secondary Amines’\(^\text{(109)}\) Microwave-assisted, vapor-phase acid hydrolysis of natural water samples for measurements of individual dissolved combined amino acids (DCAA) was examined and related to standard liquid-phase hydrolysis. The microwave technique allowed the labor-saving, simultaneous hydrolysis of 20 samples in 20 min. Relative to liquid-phase hydrolysis, a higher reproducibility and lower blanks were obtained with this procedure. In some samples, the microwave vapor-phase hydrolysis produced ≤39% higher DCAA concentrations than did the liquid-phase hydrolysis.

- ‘Flow-injection Spectrophotometric Determination of Acetylsalicylic Acid in Tablets After Online Microwave-assisted Alkaline Hydrolysis’\(^\text{(110)}\) A known mass of powdered tablets, corresponding to 500 mg of acetylsalicylic acid (aspirin), was dissolved in and diluted with H\(_2\)O. A portion (250 µL) of the resulting solution and 250 µL of 0.2 M NaOH were simultaneously injected into two separate aqueous carrier streams (both 3.4 mL min\(^{-1}\)). The two streams were merged synchronously before being passed through a 200-cm reactor coil housed in a microwave oven operated at 600 W. After irradiation, the solution was passed through a 100-cm coil immersed in a water-bath and was then mixed with a reagent stream (1.3 mL min\(^{-1}\)) of 0.5% iron(III) nitrate in 0.4 M HNO\(_3\) and the absorbance was measured at 525 nm. The results obtained agreed with those obtained by titrimetry.

- ‘Hydrolysis of Phytic Acid by Microwave Treatment: Application to Phytic Acid Analysis in Pharmaceutical Preparations’\(^\text{(111)}\) An investigation of the use of a microwave-assisted technique for sample preparation in the analysis of phytic acid in pharmaceuticals, based on its hydrolysis to phosphate and subsequent analysis by spectrophotometry, is described. Ground tablets (15–20 mg) were suspended in 50 mL of H\(_2\)O with magnetic stirring for a few minutes. Portions (0.5–2.2 mL) of the resulting suspension were transferred to a PTFE vessel, 0.2 mL of 5.3 M HCl was added and the mixture was diluted to 2.4 mL with H\(_2\)O. The reactor was transferred to a domestic microwave oven, then the oven was sealed and heated at 650 W for six 2-min periods. The reactor was allowed to cool between each heating period for alternating 20- and 40-min intervals and finally to room temperature.

- ‘Microwave-induced Rapid Transmethylation of Fatty Acids for Analysis of Food Oils’\(^\text{(112)}\) A 3-mL sample of vegetable oil in toluene (0.01 g mL\(^{-1}\)) and methyl heptadecanoate (3 mg mL\(^{-1}\)) internal standard and appropriate quantities of 0.3 or 1%
sodium methoxide in methanol in a PTFE vial were irradiated in a microwave oven or placed in a heating block. Reaction was stopped with 0.1 mL of acetic acid. Transesterification was completed in 40 s in methanol–toluene (1:10) and in 15 s in methanol–toluene (1:3) and the procedure gave a yield of fatty acid methyl esters comparable to or higher than that obtained by the conventional method and was sufficiently mild for the analysis of oils rich in polyunsaturated fatty acids.

- ‘Extraction of Selected Drugs from Serum Using Microwave Irradiation’. MAE of selected drugs from human blood/serum was performed in an ‘atmospheric pressure’ system. Before irradiation with microwaves, an appropriate solvent mixture was added to the buffered specimen. Lidocaine, methadone, diazepam, nordiazepam, propoxyphene and norpropoxyphene were tested as model substances. The final analysis was performed by gas chromatography/nitrogen–phosphorus detection (GC/NPD). The procedure had been applied successfully in a number of forensic cases.

- ‘MAE of Free Amino-acids from Foods’. MASE was used to separate free amino acids from foods. The MLS Mega microwave sample preparation system permitted concurrent extractions from ten 5-g samples into aqueous 7% HClO₄. Foods extracted were salami, cheese, broccoli and cauliflower. Optimum extraction temperatures were 40°C for vegetables and 50°C for higher fat foods. Comparative results were tabulated for extraction of up to 17 amino acids by microwave extraction (20-min analysis time) and traditional extraction by shaking. The microwave procedure yielded 5–10% more amino acids from each product.

- ‘MAE of Taxanes from Taxus Biomass’. Taxanes, including paclitaxel, were extracted from Taxus needles by MAE with an MES-1000 extraction system. Conditions were optimized with 95% ethanol as solvent, 85°C and time 9–10 min. Advantages over the conventional overnight soaking extraction method were reported. Recoveries were similar to those obtained with the traditional method.

- ‘Extraction of Incurred Sulphamethazine in Swine Tissue by MAE and Quantification without Cleanup by HPLC Following Derivatization with Dimethylaminobenzaldehyde’. Samples (freeze-dried or wet tissues) were irradiated in methanol for 25 s in a household microwave oven. After filtration, sulfamethazine (sulfadimidine) was determined by HPLC. The results agreed well with those obtained by a homogenization technique for freeze-dried samples.

- ‘Development and Validation of MAE of Fortified and Incurred Chloramphenicol Residues in Egg Albumin and Yolk’. A sample of egg equivalent to 1 g of nonlyophilized egg (containing 0.58 g of yolk per 0.3 g of albumin) was microwave extracted with 15 mL of acetonitrile and 2 mL of 2-propanol. The residue was re-suspended in acetonitrile–2-propanol (15:2) and the supernatant was decanted. The combined extracts were centrifuged, the new supernatant was evaporated to dryness and the residue was dissolved in ethanol. Recoveries from conventional and MAE are compared.

5.5 Mineral and Ceramic Samples

Geological samples are included in this section.

- ‘Determination of the Platinum-group Elements in Geological Materials by ICPMS Using Microwave Digestion, Alkali Fusion and Cation-exchange Chromatography’. A new method for the determination of platinum group elements (Ru, Rh, Pd, Ir, Pt) in geological samples, using microwave-assisted acid digestion and alkali fusion, separation of the elements by cation-exchange chromatography and analysis by ICPMS, is described.

- ‘Microwave Treatment of Minerals – A Review’. This is a short review with 25 references of the advances in the microwave treatment of minerals from the early stages of development to possibilities for future utilization. It is included since it gives some ideas which suggest a number of analytical applications. Many different applications are considered, including fundamental heating rate studies, microwave grinding, possible exploitations in the area of extractive metallurgy and also microwave treatment of coal. Further indications of the potential for the common exploitation of microwaves within the mineral processing and extractive metallurgical industries are included.

- ‘Potential of Water for Continuous Automated Sample Leaching’. This summary describes the use of water as a leaching agent in discontinuous and continuous solid–liquid extraction procedures. The ways in which new methods have improved earlier ones are discussed. The use of ultrasound and microwaves is considered, with particular reference to the use of high pressure and temperature for accelerating leaching with water under sub- and supercritical conditions (45 references).

- ‘Microwave-assisted Acid Dissolution of Sintered Advanced Ceramics for ICP Atomic Emission
A Method for Decreasing Metal Ion Content in Microwave-assisted Sample Preparation and Pre-decomposition of Coal Under Microwave Irradiation. 

### 5.6 Industrial Samples

- **Decomposition of Coal Under Microwave Irradiation**. This article describes a proposed industrial process for the decomposition of coal in a CH₂ atmosphere under microwave irradiation. It is included to spur analytical adaptations of this interesting process. 

- **A Method for Decreasing Metal Ion Content in Chemical Compounds with a Dipole Moment or a Mixture of these Compounds by Microwave Chemical Compounds with a Dipole Moment or a Mixture of these Compounds by Microwave Distillation**. The frequency of the microwave radiation used in the distillation is 1 MHz–50 GHz, and the metal ion content in the title compound(s) was decreased to ≤1 ppb. The compounds studied include HCl, HF, H₂SO₄, HNO₃, HOAc, aqueous NH₃, acetone, MeOH, EtOH, PrOH, N-methylpyrrolidone, propylene glycol monoethyl acetate and propylene glycol monoethyl ether. The distillation vessel has a casing of electrically conductive material such as steel, Cu, Al, Ni, Cr, Ti, Ag or Au. The method is used in the semiconductor industry and is included here for potential analytical applications.

- **Open-vessel Microwave Digestion of Wear Metals in Lubricating Oil**. The Star 2 microwave decomposition system (CEM, Kamp-Lintfort, Germany) is described. With use of this apparatus, oil samples were decomposed with sulfuric and nitric acids and subsequently with HCl and hydrogen peroxide by programmed heating to a maximum temperature of 280°C. Decomposition took 30 min. Cu, Fe, Ti and Pb in the resulting solution were determined by ICPAES. The results obtained on a ‘wear metals in oil’ reference material agreed with the certified values.

- **Chemical Characterization of Municipal Solid Waste Incineration Residue: Dissolution of Elements with a Microwave–Dilute Acid Digestion Technique Compared to Conventional Methods**. The focused microwave technique in an open system for the rapid dissolution of elements in fly ash and filter cakes was evaluated in comparison with conventional wet and dry methods. The method involved a 15-min heating time in 2 M nitric or hydrochloric acid. It was tested on different types of samples and led to the dissolution of Ca, Na, K, Zn, Pb and As with 2 M HNO₃ or HCl, and Hg with 2 M HNO₃ for subsequent determination by AES or AAS. The results justify the adoption of the new method.

- **Dissolution of Polymers Bearing Acid Groups Using Microwave Radiation**. The polymers studied can be dissolved in H₂O using microwave radiation much more readily than by conventional means. Placing 2.5 g of sulfonated (51%), milled polyether ether ketone (PEEK) and 47.5 g of H₂O in a microwave autoclave, flushing with N₂, subjecting the apparatus to microwave radiation for 5 min, cooling and centrifuging resulted in 98.3% dissolution, the molecular weight of the polymer being unchanged.

- **A Rapid Method for the Determination of Trace Element Impurities in Silicone Oils by ICPMS After MAD**. A MAD procedure has been developed for the treatment of silicone oil samples. ICPMS was used to determine the concentration level of 40 trace element impurities.

- **The Analysis of Coal Tar Pitch by ICP Optical Emission Spectrometry After Digestion in a Microwave Oven System**. A controlled microwave heating and digestion method was developed for the dissolution and preparation of samples of coal-tar pitch prior to...
to analysis by ICP optical emission spectrometry. A clear solution indicated minimal residual carbon levels, whereas partially digested solutions tended to give yellow solutions.

5.7 Microwave-assisted Sample Drying

- ‘Microwave Vacuum Drying of Marine Sediment Prior to Analysis for Carbon and Metals’. Errors that arise during an intermediate step in the analytical procedure of sediment drying are considered. Microwave drying in vacuum was used to reduce the boiling temperature of water and prevent loss of volatile species. The key issues in the study relate to the accuracy and precision of this process, reflected by comparison with the established oven drying procedure at 105°C.

- ‘Sample Preservation for Determination of Organic Compounds: Microwave Versus Freeze-drying’. In a search of a reliable drying method, which might be used even under field conditions, microwave drying was compared with freeze-drying of plant material. Certain leaves, buds and phloem were used and checked for one or more of the following substances: sugars, sugar alcohols, organic and amino acids, total nitrogen and glycinebetaine. With most samples good agreement was achieved between the two drying methods. Only in the case of Ananas comosus leaves, which exhibited low pH and high water content, did appreciable differences occur in organic and amino acids. For Ananas comosus leaf samples it was shown that microwave drying could also be used prior to extraction of tissue sap.

- ‘Determining the Water Content of Aggregate and Freshly-mixed Concrete by the Microwave Method’. A new standard method for determining the water content of concrete was developed and compared with the conventional spirit-drying method. The effects of the water/cement (w/c) ratio, plasticizers, concrete consistency, cement strength and further influencing factors on the quality of the analytical results were studied. Using the microwave method, the water content can be reliably determined up to 90 min after water addition, if the concrete is thoroughly homogenized, and the thickness of the sample is ≤15 cm. For concrete containing high-strength cement, 1000 W of microwave power are required to remove water completely (90 min after mixing). In contrast to the spirit-drying method, the core moisture and the water content of the additives are also determined. The reproducibility of the analytical results obtained from the microwave method was comparable to or better than that of the conventional technique.

5.8 Microwave Fusions

There has been far less use of microwave energy to bring about the fusion or sintering of analytical samples than the potential of this technique warrants. Therefore, several examples illustrating the versatility and effectiveness of microwave fusions or sintering processes are given in this section in the hope that readers may be encouraged to develop new fusion protocols for difficult samples.

- ‘Microwave Melt Texturing of Bulk YBCO Superconductors’. The potential for the use of microwave irradiation as an alternative energy source for the melt texturing of bulk, ceramic high-critical temperature YBCO (Y−Ba−Cu−O) superconductors has been investigated with a view to taking advantage of the opportunities presented by this novel heating technique. T-shaped samples of 83% dense, sintered YBCO were melt-processed, both conventionally and using microwave energy, while suspended within two different casketing arrangements. Samples consisting of densely packed, 150-μm long grains all aligned with the axis of the sample could be obtained under the best conditions. In addition, completely uniform and full oxygen lattice occupancy (X = 7 in YBa2Cu3Ox) could be obtained with all the microwave-processed samples when the melt processing temperature was kept in the range 910–940°C. However, on the negative side, this appeared to limit the maximum density to 94% of theory unless a slight drop in x to 6.98 could be tolerated. The higher processing temperatures, which yielded the best microstructures, also resulted in 5–8% of the 211 phase being present.

- ‘Accelerated Sintering and Phase Transformation of TiO2 in Microwave Radiation’. The sintering process and phase transformation of submicrometer powder compacts of TiO2 were investigated using 2.45-GHz microwave radiation. The microwave-sintered samples were densified more rapidly and in a much shorter time and at a lower temperature than that of the conventionally sintered samples. Also, an accelerated phase transformation from anatase to rutile was observed in microwave processing when the dwelling time was reduced from 6 h for conventional heating to 30 min for microwave heating at 1000°C. The samples sintered in microwave radiation show a refined microstructure and smaller grain sizes at high density near 98–99% of the theoretical value. The reasons for rapid heating behavior and enhanced sintering of TiO2 under microwave radiation are discussed.

- ‘Analysis of Heat Generation in a Conductive Polymer in Single Mode Microwave Welding’. Examples illustrating the versatility and effectiveness of microwave fusions or sintering processes are given in this section in the hope that readers may be encouraged to develop new fusion protocols for difficult samples.
Microwave welding of plastics can be achieved by placing a conductive polymer heating element at a joint interface. This heating element absorbs the microwave energy and converts it into heat, which determines the heat generation and peak temperature during welding. Hence it controls the welding cycle and final joint strength.

6 CONCLUDING REMARKS

Although only relatively recently developed, the microwave-assisted dissolution technique is rapidly becoming the method of choice for the routine handling of large numbers of analytical samples. Although the approach does not so far provide a universal sample preparation technique, it does offer certain advantages over conventional dissolution techniques. For example, the rate-determining step for sample throughput is usually sample preparation. Microwave-assisted dissolution techniques offer a reasonably economical solution to this problem. As the result of saving time, these techniques are also generally more economical in the long run, through savings due to reduced labour costs. Also, these techniques often require smaller amounts of sometimes expensive reagents, can contain corrosive fumes, thereby preventing contamination and loss of volatile elements, require less supervision, are simpler and more efficient and have proven to be reliable.

Another major advantage of the speed with which microwave-assisted dissolutions occur is that this can lead to rapid availability of results. Modern process control often requires constant monitoring of analytical parameters – these are sometimes available via on-line X-ray fluorescence (XRF) analyses, but often AAS or ICP results are needed, so that a rapid sample dissolution method becomes a necessity for efficient plant operation.

Techniques involving microwaves are not without faults, albeit they can be minimized. One disadvantage when compared with the use of open digestion vessels is that dissolution variables such as sample weight and type, acid volume, microwave power, microwave distribution homogeneity and duration of exposure must be collectively acknowledged and controlled with all due respect to the possible explosive nature of the method. However, such control itself is advantageous since dissolution conditions are accurately reproduced without surpassing vessel limitations. In addition, analyte accuracy and precision limits within batches of samples should be reduced owing to this reproducibility.

Microwave-assisted dissolutions, although relatively rapid, do themselves have one disconcertingly slow step. This is the necessary delay in opening closed vessels with high internal pressures. These must be cooled to room temperature in order for this pressure to be reduced to a safe level. Several methods of shortening cooling times have been investigated, such as internal vessel cooling systems, refrigeration or use of a freezer or cooling in ice, water or some other cold material such as liquid nitrogen. However, the time required for cooling of vessels by whatever method is only a minor inconvenience when considering how much time can be saved in performing dissolutions. For example, it takes 24 h for the complete dissolution of wool using classical methods whereas only 8 min are required using microwave digestion; this is 180 times faster!

The usefulness of microwaves in analytical chemistry is increasingly evident. From a meagre start in the 1970s represented by only seven references, publication had increased to 132 references in the 1980s and to 166 references in only the first four years of the 1990s! This review is a small selection of some of the most significant papers in the last 2–3 years, and yet covers ~90 such papers. The growth rate is increasing ever more rapidly, reflecting a wide acceptance of a variety of microwave-assisted sample preparation techniques. Microwave energy has proven to be useful in shortening drying, extraction, Kjeldahl determination, ashing and fusion times and also in increasing efficiency. Microwave techniques are also exceptionally applicable to continuous flow and on-line systems owing to their simplicity and ease of use. One or two such systems are now commercially available and have passed the prototype stage. Within the next few years, flow-through protocols will most likely replace many of the closed-vessel methods described above in high-throughput situations.

Multivariate and Hyperspectral Image Analysis

Paul Geladi
Swedish University of Agricultural Sciences, Umeå, Sweden

Hans F. Grahn
Karolinska Institute, Stockholm, Sweden

Multivariate image analysis (MIA) and hyperspectral image analysis (HIA) are methodologies for analyzing multivariate images, where the image coordinates are position (two or three dimensions) and variable number. Multivariate/hyperspectral images can have typical sizes $1024 \times 1024$, $512 \times 512$, $256 \times 256$, etc. and have between two and many hundreds of variables. The variables can be wavelength, electron energy, particle mass, and many others. Classical image analysis concentrates mainly on spatial relationships between pixels in a gray level image. MIA/HIA concentrates on the correlation of structure between the variables to provide extra information useful for exploring images and classifying regions in them. The many variables can be transformed into a few latent variable images containing condensed information. The sheer size of the data arrays necessitates visualization of raw data, intermediate data, model parameters, and residuals. When the images consist of continuous spectra having more than 100 variables, the name hyperspectral is used and the emphasis of the analysis is often on the spectral interpretation.

All physical techniques for measuring materials can be made into imaging techniques, describing not only a property but also its position in a plane or volume. All imaging techniques can be expanded to become multivariate/hyperspectral. Multivariate imaging is used in many fields of research, but for practical reasons a subdivision in the classes remote sensing, medical imaging, and microscopy (including macrosopy) can be made. In microscopy, MIA/HIA can be used to study materials and biological processes by optical, electron, and charged particle techniques.

1 INTRODUCTION

In analytical chemistry, titration and making solutions are examples of important operations that rely on homogeneous solutions containing a constant concentration of the analyte of interest. In nature and industry, gradients are important: all biological processes rely on heterogeneous environments, many manufacturing processes deal with heterogeneous mixtures and gradients, and geology deals with systems that are heterogeneous. The interpretation of data from homogeneous solutions of constant concentration or activity is rather simple. For a heterogeneous situation, a more complex representation is needed and some systems to be analyzed can only be understood by mapping in two, three, or even more dimensions. Early applications of this are found in geological and geochemical mapping\(^1\) and early clinical X-ray photography, which is a chemical map of calcium phosphate concentrations in the body.\(^2\)
The availability of electronics and computing has increased the use of mapping of heterogeneous systems, especially with the advent of satellite imaging, providing images as data files with intensities on which mathematical and statistical methods can be applied for error correction, contrast improvement, data extraction, and many other operations. Digital image analysis has evolved rapidly, but is mostly applied to one gray level image, where the spatial information in the images is explored.

It did not take long for scientists to realize that spectral information is available in imaging and to acquire data with many layers of gray level images. Satellite imaging soon began to use more than one wavelength band, electron microscopists used many X-ray wavelengths, and optical microscopists started using color and even more wavelengths outside the visual range such as the ultraviolet (UV) and infrared (IR).

This article is concerned with the use of multivariate spectral images combined with spatial exploration. Multivariate statistical methods and linear algebra are used to handle the huge amounts of data present in multivariate images. The large amounts of resulting data also are best displayed as images. Images need to be explored both in geometrical and spectral space.

Classification and detection of gradients in images are important and calibration against external information is sometimes necessary.

Section 4 discusses image formation in two dimensions (planes) and three dimensions (volumes) and Section 5 deals with multivariate image formation. Four examples are used to show the vital aspects of MIA. Their explanation is spread out over Sections 5, 6, and 7. Section 6 concerns statistical analysis and Section 7 is about visualization, but both topics overlap.

2 IMAGES AND PICTURES IN THE SCIENCES

The human eye is an organ that can process huge amounts of complex information in parallel. Because of this, illustration has always played an important role in describing technological processes and scientific principles. In the ancient cultures, Egyptian frescoes and Greek pottery explain a lot about processes of agriculture, medicine, architecture, and manufacturing. Cave paintings are even older. They date from a time when written language did not exist and the only record of activities in those days is an interpretation of the drawings. During the renaissance, artists like Leonardo da Vinci and Albrecht Dürer perfected technical painting and drawing while scientists like Andreas Vesalius, Olof Rudbeck, and Carl von Linne explained their work by technical drawings. Exploration of the seas and continents increased the accuracy and precision of map making. Microscopes were invented and the most obvious way of representing results of microscopic studies was visualizing them with geometrical accuracy and in color. Visualization using images has always been an integral part of scientific work and its use is constantly increasing.

Much of the early work in drawing and visualization was very tedious and was therefore soon replaced by photography, but the introduction of electronic imaging by television cameras with recording on video tape was necessary to make images practically useful for analysis. The possibilities were even more enhanced with the advent of digitization and storage of images as computer files, allowing automation in registration, storage, database management, and analysis. A good historical overview is given by Johnson. The color TV camera is nowadays replaced by multivariate and hyperspectral imaging devices and terabytes of data are collected daily in both airborne and medical imaging.

3 IMAGES AND COMPUTING

3.1 The Digital Image

Figure 1 gives one possible setup for collecting digital images. A video camera registers a scene through an objective and the video signal is then digitized to become data file. A digital image is an array of \( i = 1, \ldots, I \) lines and \( j = 1, \ldots, J \) columns where for each pair of coordinates \((i, j)\) a gray value is given as seen in Figure 2. This is also called raster data. A similar definition for a 3-D (three-dimensional) image is given in Figure 3. This cube is also called the hypercube. The digital representation makes it possible to carry out complex and calculation-intensive transformations. Some transformations are meant to reduce noise or take away systematic errors and others are meant to improve the visual quality of the image. This is called image processing. It is also possible to reduce a digital image to fewer parameters. This is called image analysis. There is a large literature on these topics. One example is particle sizing where images of bright particles on a dark background are collected. Thresholding on a certain gray level makes it possible to separate the bright particles from the dark background to create a binary image with white = particle and black = background (see Figure 4 for a simplified representation). In this binary image, the particles can be counted and measured, resulting in histograms of particle size, area, perimeter, etc. It is also possible to measure form factors (round, elongated, needle-like, etc.) and present these as histograms. Such operations can be
done visually, and the human eye is extremely good at recognizing products by their shape, color, texture, size, but accurate measurement requires precise, sensitive measurement systems, and huge amounts of material, and fast analysis demands require automation. Therefore, storage formats and database issues are an integral part of image analysis considerations. A multivariate image consists of more than one 2-D plane or image. These could be the same object imaged at different times or in different wavelengths as shown in Figure 5. A more formal definition follows later.

3.2 Image Storage Formats

There is still a flurry of different file formats for pixel-based images. Many are based on fulfilling specific demands and each has a good reason for existing. However, demands on industry standards for image file formats are becoming more important. Real multivariate image standards are still not well established, although one could consider the RGB (red–green–blue image) format for color images as a primitive multivariate format. There are also many formats for movies (image sequences), but much of advanced image analysis is done on still images and formats and some of these are mentioned here. Lossy compression is not considered appropriate when subsequent analysis is envisioned, but some future compression developments may be less harmful for calculations. A good overview is given in the literature.\(^{12,13}\) A possible multivariate image format is shown in Figure 6.
Figure 6  Schematic representation of a possible multivariate image file format.

The TIFF (tagged image file format) was created by Aldus, Microsoft, and NeXT and it can be used for raster images for black/white, grayscale, or color. There are four types of TIFF image: gray level TIFF images, RGB TIFF images, which contain colors based on the RGB color model, the CMYK (cyan magenta yellow and black image) TIFF images where separated image information is stored for printing color separations, and CIE (Commission Internationale de l’Eclairage) TIFF images, which contain dot-created image data in an independent unified color model. The TIFF format supports the LZW (Lemfel Zif Welsh) compression, which is a lossless compression technique. The TIFF format is an almost universal image format for photos and scanned graphics. TIFF contains the image and a relatively simple screen preview. The format is quite robust and is used extensively.

Joint photographic experts group (JPEG) is often used to show images for hypertext markup language (HTML) documents on the World Wide Web. All information about the image coding is kept in JPEG images. The lossy compression technique used for JPEG is very efficient in compressing the size of document, a process which removes “unnecessary” data in the image.

The raw format is a flexible format that is being used to transfer various documents between different programs and computer platforms. The format consists of some bytes that describe the color coding of the document. Each pixel is described in binary file format where 0 means black and 255 means white. The format also contains information that identifies the document and additional channels that can be included. The raw format needs no special byte for coding, and it can have more than 1 byte per pixel.

Recent developments in medical imaging make use of the possibilities that the large-scale image distribution offers through networking. The majority of medical imaging modalities such as magnetic resonance imaging (MRI), X-ray computed tomography (CT), and ultrasound all produce digital images. The images are stored in digital archives and can be accessed by various institutions, radiologists, and physicians.

In medical imaging, the two large organizations, American College of Radiology and National Electrical Manufacturers Association (ACR/NEMA), have defined a common file format and communication standard, the digital imaging and communications in medicine (DICOM) standard. The purpose of a common standard in medical imaging is to increase interoperability between biomedical imaging modalities such as ultrasound equipment, various modalities based on X rays, MRI with associated text, and measurements and waveforms in an electronic method of communication. Manufacturers are using the DICOM standards in the design of their imaging equipment.

Hyperspectral images are usually very large, usually up to several hundred megabytes. Since the size creates a practical complexity, the data are often stored in a compressed mode. A well-known raw data format is the environment for visualizing images (ENVI) format, where two files are stored for each dataset: one raw data file and a header file. This seems to be a general trend; the values are stored as long binary sequences with a header file to allow reconstruction of the image hypercube. A lot of software allows easy transformation of file formats, e.g. to the popular MATLAB format.

Compressed file formats such as compressed National Imagery Transmission Format (NITF), enhanced compression wavelet (ECW), and JPEG2000 are loaded into memory by a C++ library called Geospatial Data Abstraction Library (GDAL). Also the libecw2 library from ERMapper can be used for JPEG2000 images that have been embedded into other formats such as the NITF. There is a constant variation and addition that changes the file formats and these changes are usually driven by various applications.

4 IMAGE-FORMING ANALYTICAL EQUIPMENT

4.1 Plane Images

Plane images are formed by two major techniques: projection and scanning (see Figures 1 and 7). Hybrid techniques are also possible. A simple example of this is
The sample moves and the coordinates and signal from the detector are combined into a digital image.

Figure 7  Scanning registration with one radiation source and one detector. The sample moves and the coordinates and signal from the detector are combined into a digital image.

Acoustic signals can also be used for imaging materials. In summary, one might conclude that wherever there is a technique that allows study of a material by physical principles (such as interaction with radiation, mechanical vibrations, etc.) it is possible to devise an imaging technique based on projection or scanning.

4.2 Volumes

In airplane photogrammetry, stereoscopic or depth viewing is made possible by stereo photography. Some satellite systems also allow stereo images and depth information. In medical imaging, slices through solid objects are made by the technique of X-ray tomography, also called CT scan. By taking different slices, a volume can be constructed. A similar technique is applied to MRI, giving slices and volumes. By using radioactive markers, the techniques of PET (positron emission tomography) and SPECT (single photon emission computed tomography) can give information from inside a volume. The general theory of tomography is discussed by Herrmann.

Stereoscopic imaging and mechanical slicing with measuring of the slices are used both in optical and electron microscopy. An important new technique is...
confocal imaging. Confocal microscopy is based on the fact that optical focusing is in a narrow layer and that unsharp images of the other layers interfere in a thick specimen (see Figure 8 for the principle). There are two major techniques of confocal microscopy: scanning and computing. The scanning technique is based on a narrow beam of radiation (illumination), often a laser and an aperture restricted detection as shown in Figure 8. The illumination and detector beam paths overlap by a very small volume that can be moved around in the sample under study. By scanning the whole volume, a 3-D image is created. Scanning can be done either by laser scanning or by moving the sample around. This works especially well for fluorescence. The computing confocal technique makes use of 3-D blurring functions and deconvolution to make planes of sharp images in the volume. See, for example, the books by Kriete, Shotton, Corle and Kino and Stevens et al. for more details. The confocal microscopy technique relies heavily on not having too many opaque objects in the sample.

In the SIMS technique, the ion beam sputters away layer after layer of material and this can be used to do depth imaging and to construct 3-D volumes. To represent and analyze 3-D volumes of voxels, see, for example, the books by Kriete and Lohmann.

5 OBTAINING MULTIVARIATE/HYPERSPECTRAL IMAGES

5.1 Definitions

A multivariate/hyperspectral image is an image where each pixel or voxel is represented not by one gray value, but by a vector of gray values. From now on, “multivariate” and “hyperspectral” are referred to as hyperspectral. This simplifies the text without creating confusion. In many cases the vectors are spectra. With 2-D images, the hyperspectral image is a stack of gray level images, one for each variable (e.g. wavelength) (Figures 5 and 9). Congruence is very important for such a stack. This means that wavelengths for the same pixel represent the same position in the object studied. The easiest way of representing this is as a three-way or 3-D array where two of the ways are image coordinates and the third way contains variables. The indices are $i = 1, \ldots, I$ and $j = 1, \ldots, J$ for the pixel locations and $k = 1, \ldots, K$ for the variables. In satellite images, the variables are called channels or bands. For 3-D images this becomes more complicated because of the difficulty of showing four-way arrays (indices $I, J, K$ for the voxel positions and $L$ for the variables). Usually the parallelepipeds are shown under or beside each other as in Figure 10. Sometimes a system evolves over time and images are taken as a time series (just like a movie). This may be necessary in order to follow a crystallization, an erosion process, or a biological process on a microscopic scale. Arrays as described here are generally called N-way arrays. A univariate 2-D image is a two-way array; a 3-D image is a three-way array, etc.

There are two classes of variables: homogeneous and heterogeneous. A stack of images taken at increasing wavelengths is a hyperspectral image with homogeneous variables. A stack consisting of a magnetic resonance image, an X-ray image, and an ultrasound image of the same object is a hyperspectral image with heterogeneous variables. For homogeneous variables, it is relatively easy to obtain congruent images in the stack. For heterogeneous variables, a transformation may be needed to achieve congruence of the images. Also, the intensity and spatial resolution may vary widely between techniques for heterogeneous variables.

A color image is multivariate since there are three color planes needed to construct it. For television these are red, green, and blue and for photography they are
A multivariate 3-D image is a four-way array with indices $H, I, J$ and $K$. It may be represented by writing $K$ three-way arrays in a sequence.

A color image on a screen is produced by mixing images in the red, green, and blue channels. If the data in the images are true red, green, and blue, almost true colors are produced. If any other combinations are used, a distorted color results.

Figure 10 A multivariate 3-D image is a four-way array with indices $H, I, J$ and $K$. It may be represented by writing $K$ three-way arrays in a sequence.

Figure 11 A color image on a screen is produced by mixing images in the red, green, and blue channels. If the data in the images are true red, green, and blue, almost true colors are produced. If any other combinations are used, a distorted color results.

Red channel (or magenta)
Green channel (or yellow)
Blue channel (or cyan)

Color/pseudocolor image

Figure 12 An image of a sample measured by scanning electron microscopy in two variables: backscattered (a) and secondary (b) electrons. The image size is 256 × 256.

5.1.1 Examples 1 and 2: Electron Microscopy and Secondary Ion Mass Spectrometry Data

Figure 12 shows congruent images obtained by electron microscopy. One image is for backscattered electrons (no energy loss) and the other one is for secondary electrons (energy loss by interaction with the sample). Figure 13 shows a multivariate image obtained by SIMS. There are nine $256 \times 256$ congruent images representing the intensity values for selected isotopes of the elements Na, Mg, Al, Si, Cr, Fe, Ni, Cu, and Zn. The sample is a corroded metal wire of 0.2-mm diameter. If the images of Figures 12 and 13 were made congruent by some transformation, the resulting multivariate $11 \times 256 \times 256$ image would have heterogeneous variables: two electron intensities and nine $m/z$ values.

5.2 Variables

Many variable types can be used to produce 2-D and 3-D hyperspectral images. It is useful to consider three major fields of image analysis: remote sensing, medical applications, and analytical chemistry. The emphasis is on analytical chemistry, but for historical reasons some remote sensing and medical applications are also mentioned. Table 1 gives some variables used in imaging. The table is not complete and new developments appear...
Figure 13  SIMS images for nine elements form a $9 \times 256 \times 256$ multivariate image stack. (a) Na, (b) Mg, (c) Al, (d) Si, (e) Cr, (f) Fe, (g) Ni, (h) Cu, and (i) Zn.

continually, but it gives a good overview of the major concepts and their mode of use.

Airborne imaging from balloons and airplanes on black and white, color, and IR film is a very old technique and has given rise to the important field of photogrammetry. The first weather satellites were launched during the 1960s. Satellite and airborne imaging are used in agriculture, geology, hydrology, urban planning, climate studies, archeology, etc. Over the years different systems have been employed, and a good historical overview is given by Lillesand and Kiefer. More details are also found in Sabins and Horst.

Satellite imaging works continuously with automatic gathering of data for as long as the satellite works, which usually is a number of decades. Airborne imaging is based on scheduled flights of a shorter duration. VIS, NIR, IR (collectively called optical), and radar (or microwave) wavelengths are used. Table 2 gives the wavelength bands of some important systems capable of giving multivariate images. The optical systems are passive, depending on reflection of sunlight while the radar systems are mainly active, meaning that the exciting radiation comes from the satellite. Radar waves are insensitive to clouds and atmospheric phenomena and work during both day and night. Many optical satellites have orbit patterns that follow the sunlight. For the radar systems, wavelength and polarization can be varied to produce many imaging variables. Wavelength bands range from 7.5 mm (40 GHz) to 1000 mm (300 MHz) and a popular range is the $K_u$ band: 12.5–18 GHz. More details on specific airborne and satellite systems can be found in Kramer.

The multivariate information in satellite and airborne images has also been called hyperspectral since the late 1980s and can be used to study chemical composition on the earth’s surface and just a few examples are highlighted here. The combination of microwave and optical satellite date is described by Moran et al. The detection of mineral content using optical data is found in Deroin et al. The use of high resolution airborne images for studying vegetation with respect to minerals is described in Roberts et al. and in Van der Meer and Bakker. These applications are really chemical analysis from a distance.

Imaging in medicine began when Konrad Röntgen discovered the X rays. Almost immediately (1905) the technique was introduced into diagnostic work. The technique relies on the fact that various tissues in the body absorb the X-ray beam differently. If the beam that passes through the body is trapped by a film, various gray levels will be generated, each related to the specific part of the body that has been X-ray-exposed. The technique has been film-based since the beginning and the technical procedure has not changed much over the years. With the introduction of the CR technique in the 1970s, film was replaced by photostimulable phosphor radiographic systems, which digitized images in scanners. A new era in conventional medical imaging began: images were now visualized with adjustable gray levels by a monitor and image processing tools became available. A prominent tool is edge detection, because edges characterize object boundaries. For diagnostic work, many image processing techniques received slow acceptance by radiologists because of problems with interpretation. Today, many processing tools are accepted and used frequently.

In medical applications, images can be made multivariate/hyperspectral by using different X-ray wavelengths, different MRI pulse sequences, different contrast chemicals, different ultrasound wavelengths, color television cameras (extended by UV and NIR wavelengths) in wound and skin studies, and in endoscopic studies.
With the radiotracer materials used in PET and SPECT, time-dependent diffusion and decay of the tracers give a temporal multivariate sequence. Sometimes images from different studies may be combined to form a multivariate/hyperspectral image with heterogeneous variables, e.g., MRI images with X-ray images and acoustic images. The advantage of this is that some techniques give better spatial resolution, while others give better contrast between tissue types, but with a less spatial resolution.

In parallel with the CT development the CT technique evolved. This imaging technique is, in principle, an X-ray method based on the generation of cross sections of an object from several images of its transaxial projections. The projection is basically a shadowgram obtained by radiating an object. The CT technique is nowadays considered a standard diagnostic technique for examination of any part of the body.

The MRI technique uses an image reconstruction technique based on the Fourier transform. The images received reveal the proton density in tissue. It is increasingly being used in medical imaging.

In optical microscopy, different techniques exist to make images of the same sample: brightfield (the usual technique), dark field, phase contrast, and polarized light. The illumination can be white or different wavelengths from the UV and up to the NIR. The sample can be studied in diascopic mode (transmission) or in episcopic mode (reflection or fluorescence). The latter mode makes the use of fluorescence possible. Many combinations of exciting and emitted wavelengths may be chosen. This is improved by the use of fluorescent reagents that specifically mark certain regions in a tissue.

The special microscopic techniques are IR and Raman microscopy, where a sample is studied in VIS light under the microscope and a useful region for study is found. Then, the selected region is studied by detailed laser Raman or IR spectroscopy. By scanning, image formation in IR and Raman wavelengths is possible.

In electron microscopy, many modes of operation are available and each of these provides many modes of detection. Usually, a distinction is made between transmission, scanning (reflection), and microprobe modes. Also, combinations are possible such as scanning transmission. The phenomena detected are brightfield transmission, dark field transmission, backscattered electrons, secondary electrons, electron energy, X rays, and optical emission. All these phenomena are usually affected by the energy of the exciting electrons, giving extra variables to be considered.

In ion microscopy, the SIMS technique allows direct imaging of ions by quadrupole mass spectrometry. A better mass resolution is obtained with time-of-flight mass spectrometry (TOFMS), giving fractional masses and the possibility of studying organic materials and isotopic composition. In PIXE, the charged particles (usually protons) give X-ray emission in different X-ray wavelengths that are specific for certain elements.

More suggestions on how to make imaging methods hyperspectral are presented in Geladi and Grahn and in Grahn and Geladi. In principle, all imaging methods can be made hyperspectral. With this whole plethora of possible modes of measuring samples and selecting a detected variable, there is rarely one image that provides the solution to the problem at hand. Most of the images that can be produced contain correlated information on the sample studied and, therefore, it is necessary to treat them together to obtain the maximum information from the images.

5.2.1 Example 2: Secondary Ion Mass Spectrometry Data

The SIMS example of Figures 12 and 13 has images of the sizes $2 \times 256 \times 256$ and $9 \times 256 \times 256$. It has been described in part in Van Espen et al. The technique used is described by Van Espen and Janssens. The sample is a corroded string of an antique musical instrument. The original problem was a study of the metallurgical techniques used and the nature of the corrosion. For this purpose, a part of the string was fixed in a polymer medium and polished flat. The SIMS measurements were made in a Cameca 3f instrument. The sample is excited by a thin Ar+ beam. The Ar ions produce secondary ions on impact and these secondary ions enter a mass spectrometer. The instrument has an electrostatic and a magnetic sector for mass to charge ($m/z$) filtering. The $m/z$ filtered ions are projected in focus on a fluorescent target and the intensity image from this target is read by an analog video camera and digitized. Two variables of the $2 \times 256 \times 256$ image were secondary and backscattered ion intensity, measured by scanning electron microscopy. The nine SIMS variables of the $9 \times 256 \times 256$ image were positive ion intensities at different $m/z$ as in Table 3. The images are present as $256 \times 256$ pixel image files with 256 gray levels for each pixel. This means that the ion and electron intensities had to be transformed logarithmically and stretched to fit the smaller range of 0–255. Figure 13 shows the SIMS images. Some of them have artefacts in the background due to low ion intensities.

6 STATISTICAL ANALYSIS

6.1 Pretreatments of the Data

Those who produce images try to obtain the best possible raw images by using the instrumentation properly, but

errors cannot always be avoided. Any small errors that obviously do not belong in the images are removed. Images to be used for MIA/HIA are usually corrected for errors, missing data, and excessive noise before the MIA/HIA takes place. The whole gamut of univariate image processing techniques is available for this purpose. In some kinds of images, parts may be removed completely, e.g. by filling in zeros, because it is known in advance that they are not needed. Making images congruent or of the same spatial resolution is also part of preprocessing before performing MIA/HIA. Registration is the process of making images congruent by rotation, translation, stretching, and shrinking to make fixed points (landmarks) match. This can be done in 2-D or 3-D. These techniques of correction belong to univariate image analysis and there is an abundant literature on this subject. 

6.2 Exploratory Study of Raw Images

The separate images in a hyperspectral image can be visualized as gray level images or as pseudocolor images. Usually, the image data are stretched in a linear or nonlinear fashion to obtain the best contrast and intensity conditions for the human observer. Using triplets of images to create pseudocolor is a useful way of studying hyperspectral images, but in some cases there are too many combinations to be checked. Colors can be “natural” when using a color television camera, or completely artificial, e.g. when combining electron microscopy images into color composites. A technique often used in remote sensing is ratio imaging, where the ratio between two wavelength bands is used to create new images.

Scatter plots are quite useful because they show correlations and groupings in images. A scatter plot between two images is obtained by taking intensities for matching pixel positions and using them as horizontal and vertical positions in a plot. Figure 14 shows how this is done. There are many combinations of two images selected from a hyperspectral image and looking at all combinations is not always possible. It is also possible to make 3-D scatter plots. These can be made visible in 3-D and rotated or projected to 2-D on three surfaces of a cube. Scatter plots of raw images sometimes show useful information about the individual images in a stack. Preprocessing for scatter plots is done by stretching or shrinking the intensities to the range of 0–255, or any other convenient range.

The scatter plot of the backscatter and secondary electron images in Figure 12 is shown as Figure 15. The 256 × 256 = 65 536 pixels cannot be shown as individual points, so they are given as densities of points: dark = low density and bright = high density. It can be seen that there is a clustering of pixels and that there are outlier pixels. There is also an artefact from intensity stretching in the secondary electrons image. This artefact could not be observed by studying the images themselves.

The clusters can be used to define classes in the scatter plot and these pixel classes can be projected back to image...
A number of classifiers can be used on pixel clusters in a scatter plot: the box classifier (a), the ellipsoid classifier (b), and the polygon classifier (c) are shown here.

Space for inspection. Figure 16 shows some methods of selecting subsets of pixels in scatter plots. The first method is the box classifier using rectangles or parallelepipeds (for 3-D scatter plots). The box is easily defined, but may not always be of the correct form. The second method shown in Figure 16 is the ellipsoid classifier. It is based on the assumption of multinormal distribution of the pixels in a class. The ellipsoids are class membership probability ellipsoids. The most versatile is the polygon classifier.

It can be objectively adapted to perceived shapes of the pixel classes and improved interactively to most shapes. For 3-D scatter plots, the box classifier is easily defined while the ellipsoid classifier is more difficult and the polygon method becomes quite awkward. When using polygons, they are filled to define a contiguous area, called mask or class mask.

Figure 17 shows some results of a rough classification. The classes are defined interactively by a polygon

Figure 17 A rough partition of the scatter plot of Figure 15 in four classes and back projection of the classes to image space. The classes are (a) background, (b) core, and (c, d) two corrosion product classes.
classifiers. Compared with box classifiers or ellipsoid classifiers, the polygon classifier gives a more realistic class boundary, since the true classes are rarely rectangular or ellipsoidal. It is also possible to define classes in the image and to find out where they fall in the scatter plot. The backscattered electrons (vertical axis in Figure 15) are the main contributors to the clustering, but there is also a small contribution from the secondary electrons (horizontal axis in Figure 15). This gives a small improvement over just using segmentation in one image. The major regions of the scatter plot are background, core, and two corroded regions. Some misclassification always occurs, but the main feature to look for is larger contiguous regions belonging to the same class. Single pixels and smaller regions may be misclassifications. With only two variables, this is all the information that can be extracted and there is only a little bit on chemical composition, where the backscattered electrons may reflect the atomic number. The classes are based on interaction of the sample with electrons. The SIMS images (Figure 13) may be able to give more information on chemical composition. It is always possible to refine the classification in Figure 17, but that is not shown here.

6.3 Principal Component Analysis: Latent Variable Images

The problem with hyperspectral images described above is that there are many variables to be checked and that there is usually a high correlation between them. Therefore, decorrelation is needed. This can be done easily by principal component analysis (PCA).\(^{54,55,58–60}\) PCA calculates new variables, called latent variables or scores, thereby going from \(K\) to \(A < K\) image variables. These are orthogonal and therefore they show no correlation. The latent variables also form images and therefore these are called latent variable images or score images. Another interesting property of scores is that a few latent variables describe most of the variability in the hyperspectral image and that the remaining ones show little variability and can be considered as noise and discarded. This means that a data reduction is obtained by going, for example, from 10 variables to 3 latent variables explaining over 90% of the original variability. The three latent variables obtained in this way can easily be studied in pseudocolor images or in scatter plots called score plots (Figure 18). Alternatives to PCA may be based on curve resolution or factor analysis and can be found in the literature.\(^{61,62}\) Also, hybrid algorithms using spatial information have been tried.\(^{63}\)

6.3.1 Example 2: Secondary Ion Mass Spectrometry Data

The \(9 \times 256 \times 256\) SIMS hyperspectral image was subjected to PCA analysis. The images were used as shown in Figure 13, stretched to fill the 0–255 intensity range. PCA was carried out without mean centering or rescaling of the nine variables. The results of the analysis are shown in Table 4. With four principal components, over 95% of the original sum of squares is explained. Figure 19 gives RGB composites of components 1, 2, 3 and 2, 3, 4 using the principle of Figure 11. These color images form a condensed representation of the main information in the nine original images of Figure 13. The colorings in the color composites give a good subjective overview of the different classes in the sample. The main constituents of these images are background, metal core, and corroded regions around the core. The background and metal core are homogeneous, while the corroded parts are very heterogeneous. Figure 20 gives the loading plots for the SIMS images. These explain the role of the variables in the different components. The first component has strong contributions from \(\langle\text{Zn},\text{Cr}\rangle\) and \(\langle\text{Fe},\text{Ni}\rangle\) while the second has strong contributions from \(\langle\text{Fe},\text{Ni}\rangle\). Fe and Ni are the major elements of the core of the sample. Zn and Cr seem to be a surface contamination, probably from mechanical processing. Other groupings are \(\langle\text{Al},\text{Si}\rangle\) and \(\langle\text{Na},\text{Mg},\text{Cu}\rangle\). Al and Si are usual in the earth’s crust and are an indication of contamination by sand.

6.3.2 Example 3: The Visible/Near Infrared Data

Images were collected with a PbS camera connected to a low-magnification microscope.\(^{54,64}\) The wavelengths were in the VIS and NIR regions. The setup uses interference filters and a ring of optical fibers to give a monochromatic illumination of the object under study. An overview of wavelengths used is given in Table 5. The object is a piece of chinaware that has undergone painting and glazing in different layers. The total image is \(12 \times 256 \times 256\). The original images were \(512 \times 512\),
Table 4  Results of PCA analysis on the 9 × 256 × 256 SIMS image; percentages of the sum of squares (SS) and cumulative SS are shown

but because of border errors in the NIR region with the camera, only the central part was used. The images were averaged for noise reduction and some were amplified during this averaging. The image size is 9.5 mm × 9.5 mm.

Figure 20  Loadings plots for the components 1–2 and 3–4 for the SIMS example.

Figure 21 is an RGB composite of wavelengths 460, 540, and 630 nm, which gives a reasonable impression of the colors. Table 5 also shows means and standard deviations. Two images have low standard deviation because of low transmission of the filter combined with low sensitivity of the camera. The VIS/NIR image was subjected to PCA with centering of each image, but without rescaling. PCA can give different results depending on the preprocessing of the data that is used. Image-wise (variable-wise) mean centering takes away differences in average intensity and compensates for the fact that some wavelengths may be...

a 16/16 means averaging over 16 images, 64/16 means averaging over 64 images, and increasing intensity by a factor of 4, etc.

Figure 21 A color composite of the 460, 540, and 630 nm images of the VIS/NIR image.

darker or brighter on the average than others. Image-wise scaling gives more equal contrast over the images. It is also needed when different variables are measured in different units. The general use of these operations is to avoid that any image in a stack dominates the analysis because PCA is supposed to look for correlations or covariances. The PCA results can be seen in Table 6. Three components explain a large amount of the total sum of squares and five components explain almost all the sum of squares, giving an appreciable data reduction.

6.3.3 Example 4: Hyperspectral Near Infrared Data

The hypercube of eight pieces of polymer material is collected with an InGaAs camera and an LCTF (liquid crystal tunable filter) in the range 960–1662 nm with a band every 6 nm. Illumination is with four quartz halogen lamps and the polymer pieces are positioned on a white ceramic tile in order to obtain reflectance/transfectance images. This gives a hyperspectral image (hypercube) of size 256 × 320 × 118. A background and a reference image are also collected in order to correct for noisy background from the camera and nonhomogeneous illumination. The corrected image is subjected to PCA and three score images (99.63, 0.16, and 0.11% of the total sum of squares) are obtained. This is a huge data reduction coming from 118 wavelength bands. Of the eight pieces of polymer, four are PET (polyethylene terephthalate), three are PP (polypropylene), and one is PE (polyethylene). Three pieces are turbid (nontransparent): the PE piece and two PP pieces.

Exploration and classification in many wavelengths were first used in remote sensing by Ready and Wintz. A good early overview is found in Lillesand and Kiefer. In one of the chapters, scatter plotting of raw data, box classifiers, nonrectangular box classifiers, and Gaussian maximum likelihood classifiers are explained. There is also a description of how to rotate axes to obtain better discrimination. The concepts of region of interest and unsupervised classification are introduced.

An exploration of a hyperspectral image data set starts with obtaining histograms of the images and two-image scatter plots. After that PCA gives useful information. A table or plot of percentage sum of squares explained in each component (Tables 4 and 6) is used to select the number of components that is to be kept. The components are used for making score plots, but also loading plots are useful. They allow an interpretation of the role of the variables in the model. A vast number of methods exist for classifying in a hyperspectral image. This can be done automatically, or interactively. There are different degrees of interactivity. The results of the PCA for the VIS/NIR image are shown in Table 6. Since the images in the stack are correlated, four to five components suffice to explain most of the sum of squares.

Classification can be supervised or unsupervised. In the supervised case, one is looking for known classes. In the unsupervised case, one tries to find classes in the data without prior knowledge. Supervised classification
often starts from a region of interest. The multivariate properties of this region then define the class and all other pixels are tested for class membership.

6.5 Regression and Calibration

Regression between a multivariate image and external data is a very useful technique. In satellite and airborne imaging, images over an area of 1600 km$^2$ are available, e.g. a river delta. The ground truth for water quality must be studied on the ground and even 1 km$^2$ of ground truth data is quite difficult and expensive to collect. In this case, it would be convenient if a water quality parameter could be modeled from the spectral information in the hyperspectral image. The same situation occurs in medicine, where tissue quality or disturbances such as tumors and plaque have to be modeled from hyperspectral magnetic resonance images and the “ground truth” may be a small, expensive biopsy. Multivariate/hyperspectral image regression (MIR/HIR) is about relating desirable localized external information to the hyperspectral image. This information can be qualitative or quantitative. The regression techniques used are preferably based on latent variables. Examples are given in the literature.$^{(64, 68–75)}$

6.6 Experimental Design for Imaging

With many variables available for imaging, it may be useful to select the interesting ones more carefully. Leaving out really useless or noisy variables gives quicker image collection and a saving in data storage. In medical imaging, it means less strain on the patients. In a number of cases, screening by experimental design is possible in order to decide on useful imaging variables.$^{(76)}$ Alternative techniques can be used to find subsets of useful wavelengths.$^{(77)}$

7 VISUALIZATION OF RESULTS

7.1 Latent Variable Images

Latent variable (score) images are constructed from the original images by methods like PCA, with different pretreatments. Latent variable images are constructed to have desirable properties. PCA gives orthogonality, allowing a condensation of the information in a few images. The use of score images also has noise reducing properties. Latent variable images can be studied as they are, or used as color composites (see Figures 19 and 22 for examples). The color contrasts in a color composite are subjective and they may be misleading or difficult to interpret in some cases. In other cases, they give a good impression of the different compositions in the image and their localization.

Figure 22 An RGB composite of (a) red = score 1, green = score 2, blue = score 3, and (b) red = score 2, green = score 3, and blue = score 4 for the PCA result of the VIS/NIR image.

7.2 Scatter Plots

Scatter plots of images are useful, as shown in Figure 17, but scatter plots of score images are even more useful. These are called score plots. The principle is the same as in Figure 14, but the data are more concentrated and the score images are orthogonal, giving better scatter plots. Figure 23 gives some score plots for the SIMS example. The plots are color coded for pixel density. The color coding is found in Geladi and Grahn.$^{(54)}$ The figure shows the score plots for principal components 1–4 in combinations 1–2, 1–3, 1–4, and 2–3. The score plots show two dense clusters corresponding to the background and core, and also some interesting smaller clusters corresponding to the corroded parts. An example of how to use such plots for classification is shown in Van Espen et al.$^{(56)}$ The loading plots allow a chemical interpretation of what is found in the score images and score plots.

An important loading plot for the VIS/NIR image is shown in Figure 24. It shows a good spread of the VIS
Figure 23  Score plots for the principal components 1–4 of the SIMS example. Combinations 1–2 (a), 1–3 (b), 1–4 (c), and 2–3 (d) are given. Dense clusters, smaller clusters and single pixels can be observed.

Figure 24  Loading plot of components 1 and 2 of the VIS/NIR image. Wavelengths in nanometer are indicated.

The two NIR wavelengths with small standard deviation have almost zero loadings. The loading plots of the SIMS image allow a chemical interpretation, while the loading plot of the VIS/NIR image gives a spectral interpretation, which can lead to a chemical interpretation if sufficient spectroscopic evidence is given for the sample. Score images for components 1 and 2 for the VIS/NIR example are shown in Figure 25. The first score image is greatly influenced by the NIR wavelengths, while the second one gives a “visual” impression. The NIR radiation reacts most to the metallic “gold” coloring by giving total reflection. The score plots for the VIS/NIR example are seen in Figure 26. They show a useful number of pixel classes for components 1, 2, and 3. Component 4 seems to be influenced mainly by a gradient of outlier pixels.

7.3 Polygon Segmentation

Polygon segmentation was explained for scatter plots of raw images. The technique becomes even more powerful when latent variable images are used, because scatter plots of latent variable images show even better clustering of pixels and more separation of the clusters. A simple example is in order. Figure 27 shows the score plot of components 3 and 2 for the VIS/NIR image. A polygon classifier is used by putting a mask on the score plot to cover selected pixels. The pixels under this mask are then projected back to the image where they are highlighted in white (other colors are possible). The highlighted pixels
Figure 25  The first (a) and second (b) component of the VIS/NIR image. These are score or latent variable images.

Figure 26  Score plots for the principal components 1–4 of the VIS/NIR example. Combinations 1–2 (a), 1–3 (b), 1–4 (c), and 2–3 (d) are given. Dense clusters, smaller clusters, gradients, and single pixels can be observed.

are the red class, corresponding to the red dye used in painting the porcelain. The classification can be refined by modifying the polygon mask. In this way a number of classes can be defined, until most of the area in the image is classified. This classification corresponds to the different chemical compositions of the colored areas. In some regions, the coloring is homogeneous, while in other regions it is heterogeneous, indicating that many strokes of different colors were used to create a visual effect. The visual wavelengths are most important, since the dyes used were meant to give a visual impression. The NIR wavelengths also give a contribution by reacting with the metallic inclusions in the glazing. Miscellaneous references on classification in multivariate images are available. (78–88)

7.4 Local Modeling

Images can be quite large and one is not always interested in analyzing the whole image. There may be large regions that are of little or no interest or only small regions that are of real interest. In medical imaging, only the patient and not the air surrounding him/her is used and even inside the patient, only a lesser region of diseased
tissue may really be worth studying. In satellite imaging, different research groups focus on different surface-based phenomena: only wetlands, only water, only forest, and only clear-cuts.

Also in microscopic techniques, details may be more interesting than the whole image, e.g. a few cells in a transparent medium or only cell membranes. There exist different techniques of neutralizing uninteresting regions or selecting only smaller regions. All the data analysis models and visualization techniques mentioned earlier can also be used with these smaller local image regions.

7.5 Hyperspectral Visualization through Score Images

Figures 28–30 are the first, second, and third score images of the corrected $256 \times 320 \times 118$ hypercube of the polymer pieces. In Figure 28, one of the pieces is slightly darker and this is a piece of PE. In Figure 29, three pieces are highlighted. The PE piece is very bright and two other pieces are also brighter. They are both PP pieces. All three pieces are made of nontransparent plastic. In Figure 30, four pieces are highlighted. These are all PE terephthalate. The information obtained is partly available by visual inspection of the pieces in white light, but the NIR spectra contribute unique spectral (= chemical) information. The classification is easily done without any prior need to know where to look for wavelength bands. The analysis shown here can be carried out in much more detail, but already the score images give an indication of the power of hyperspectral imaging in the NIR region.

8 DEFINITIONS

In image analysis, certain conventions are needed for working and communicating more easily. A proposed list is given below. More extensive and alternative definitions can be found in the literature.

- 2-D digital image: an array of intensities consisting of lines (rows) and columns, indexed by $i = 1, \ldots, I$ and $j = 1, \ldots, J$. Each $(i, j)$ pair or pixel has a number expressing intensity. The origin of the coordinate system is the upper left-hand corner. See also Figure 2. The image is also called gray level, intensity, or black and white image.

- 3-D digital image: an array of intensities consisting of lines (rows), columns and planes, indexed by $h = 1, \ldots, H$, $i = 1, \ldots, I$ and $j = 1, \ldots, J$. Each triplet $(h, i, j)$ or voxel has a number expressing intensity. The origin of the coordinate system is the upper left-hand corner of the frontal plane. See also Figure 3.

- 2-D multivariate/hyperspectral image: an array of intensities consisting of lines (rows), columns, and variables, indexed by $i = 1, \ldots, I$, $j = 1, \ldots, J$ and $k = 1, \ldots, K$. See also Figures 5 and 9. Alternatively, see 2-D digital image, but each pixel is a vector (spectrum) of values instead of a scalar (intensity, gray value).

- 3-D multivariate/hyperspectral image: an array of intensities consisting of lines (rows), columns, planes, and variables, indexed by $h = 1, \ldots, H$, $i = 1, \ldots, I$, $j = 1, \ldots, J$ and $k = 1, \ldots, K$. See also Figure 10. Alternatively, see 3-D digital image, but each voxel is a vector (spectrum) of values instead of a scalar (intensity, gray value).

- 2-D multitemporal image: an array of intensities consisting of lines (rows), columns and times, indexed by $i = 1, \ldots, I$, $j = 1, \ldots, J$ and $m = 1, \ldots, M$. The $m$-index forms a sequence in time. See Figure 5.

- Binary image: an image in which pixel (voxel) values are only black or white. The image is often used to represent classification results. See Figure 17.
Figure 28  First score image of the NIR hyperspectral image. The piece of PE plastic is slightly darker.

Figure 29  Second score image of the NIR hyperspectral image. The three nontransparent pieces of plastic are brighter.
Figure 30  Third score image of the NIR hyperspectral image. The four PET pieces are brighter.

- Box classifier: a box is used to select a cluster of pixels in a scatter plot that form a class. See Figure 16.
- Confocal: a (dark field) technique of imaging in volumes by using a narrow illumination beam and a narrow return path to the detector. All slices in the volume are in focus. See Figure 8.
- Congruence: when measuring images using different variables or techniques congruence means a one-to-one position correspondence for the pixels in the different images. Congruence is an absolute condition for making MIA possible.
- Density coding: used to show pixel densities in scatter plots. See Figures 15, 23, and 26.
- Ellipsoid classifier: an ellipsoid is used to select a cluster of pixels in a scatter plot that form a class. See Figure 16.
- Focal plane scan: a system in hyperspectral imaging, when a complete image is taken at one wavelength. The hypercube is constructed by scanning over the wavelengths using electronically controlled filters.
- Hypercube: another name for the hyperspectral image with indices \( i, j, \) and \( k \).
- Intensity resolution: many images have intensities between 0 and 255. Radiological standard is \(-1000\) to 3095. A binary image has only 0 and 1 as possible intensities.
- Image analysis: a mathematical operation that transforms an image into desired information. Often a mathematical data reduction is involved.
- Image processing: a mathematical operation that transforms a digital image to a new digital image with (almost) the same spatial and intensity resolution, by taking away noise and/or errors.
- Latent variable image or score image: an image in which the values for the pixels are the results of a PCA calculation. Composites of latent variables images are shown in Figures 19 and 22. Figure 25 shows latent variable images.
- Line scan: a system in hyperspectral imaging, when a line of spectra is scanned. The hypercube is constructed by adding lines when moving the camera or object to be scanned; sometimes also called push broom technique.
- Loading plot: a scatter plot showing the importance of the original variables in the latent variable (PCA) model by the positions of the variables in the plane. See Figures 20 and 24.
- Mask: a filled polygon used to select pixels under it (also class mask). See Figures 17 and 27.
- MIA/HIA: as image analysis, but used on multivariate images and makes use of the correlation between the images.
• MIR/HIR: regression between multivariate images or between multivariate images and external information.
• N-way array: an array of numbers, where each number has N indices. A matrix is a two-way array. A multivariate image is a three-way array, or a four-way array if it describes volume.
• Object: the entity under study by image analysis.
• Point scan: a process in hyperspectral imaging, when a complete spectrum (often Fourier transform FT) is taken in a point of an image and the hypercube is constructed by scanning the detector or object in x and y coordinates.
• Pixel: an element of a 2-D digital image. Pixels are square or rectangular. A pixel has four side neighbors and four corner neighbors.
• Polygon: a closed figure made of straight lines and corners, used to define a region of interest.
• Polygon classifier: a polygon is drawn around a cluster of pixels in a scatter plot to define a class. See Figure 16.
• Projection: the most often used imaging technique in photography, video cameras, transmission electron microscopes, etc. See Figure 1.
• Pseudocolor image: commonly used to denote a lookup table with assigned colors for gray level images.
• PCA: a technique of reducing many variables to a few meaningful latent variables. See Figure 18.
• RGB image: a color image in which three different congruent images are used to create color information in print or on a computer/video screen. The colors do not have to be true colors. See Figure 21 (almost natural colors), Figures 11 and 23 (artificial colors for latent variables).
• Raw images: images as they are collected by an imaging device. Before analysis these are usually pretreated or corrected.
• Region of interest: a region of pixels in an image or in a score plot.
• Registration: the process of making two images congruent by translation, rotation, stretching, shrinking, and warping with given fixed points (landmarks) as references.
• Sample: the entity under study by image analysis.
• Scanning: an imaging technique using a small radiation source and a small detector. The radiation source, the detector, or the sample can be moved. Many variations are possible. See Figure 7.
• Scatter plot: a plot of 2(3) vectors, matrices or other arrays in which the (horizontal and vertical) coordinates of the plotted points are given by the respective vectors, matrices, or arrays. For images, the intensities of corresponding positions in both dimensions are used as (horizontal and vertical) coordinates in the scatter plot. A scatter plot is a cloud of points in a plane (volume). With very many points, density coding is used instead of showing individual points. See Figure 15.
• Score plot: a scatter plot, where scores (latent variables) are used as input, see Figures 23 and 26.
• Scene: the entity under study by image analysis.
• Score image: latent variable image.
• Segmentation: a transformation of an image (univariate or multivariate) to a binary image containing objects for study and a background.
• Spatial resolution: has to do with the number of rows, columns (and planes) in an image.
• Tixel: a pixel of a multitemporal image.
• Tomography: a technique of reconstructing slices or volumes in 3-D objects from projections through the object.
• Variable: any physical method of extracting image information from an object. Each variable used creates a different image. The simplest example is different wavelengths.
• Voxel: an element of a 3-D image. Voxels are cubes or parallelepipeds. A voxel has 6 side neighbors, 12 edge neighbors, and 8 corner neighbors.

ACKNOWLEDGMENTS

The SIMS example was recorded by Helena Wouters of the University of Antwerp, Belgium. Piet Van Espen is acknowledged for providing the files and giving permission to use them.

Analytical methods have to meet certain quality requirements, so that the results are credible and can be used with confidence for regulatory, economic and research decisions. Analytical quality assurance (QA) contains preventive action and comprises planning steps, quality control (QC), quality assessment, documentation and quality improvement. All factors leading to the analytical result have to be controlled, clearly described and documented. Furthermore, the analytical result should be linked to the sample and related to reference materials (RMs) or measurement standards by an unbroken chain of traceability. Two elements are needed in order to achieve this goal: internal QA measures comprise elements performed by the laboratory, such as method validation and documentation and the use of RMs, external QA relates to performance evaluation by persons outside the laboratory, such as proficiency tests and accreditation.

1 INTRODUCTION

Results from analytical measurements form the basis for decisions which may have serious economic, environmental, safety and health related consequences. Confidence in these decisions therefore depends directly on the quality of the analytical results. The International Organization for Standardization (ISO) defines quality as ‘the totality of features and characteristics of a product or service that bear on its ability to satisfy stated or implied needs’.(1) Some of these demands are stated by the customer, who may be located inside a company or a public organization, others may be required by standards or laws, e.g. safety requirements. Because needs change with time, what was regarded as being of high quality in analytical chemistry some years ago may not satisfy today’s requirements. On the other hand, qualitative or half-quantitative results, for example a pH value acquired by using litmus paper, may be fully adequate for a certain task. It follows that quality is a relative concept.

In order to ensure that products or services meet defined standards of quality with a stated level of confidence, appropriate QA measures have to be taken. While traditional product-centered QC is based on the principle of checking conformance with the specifications of the final product, process-oriented QA contains preventive action and comprises planning steps, QC, quality assessment, documentation and quality improvement. QA can thus be regarded as a feedback loop (Shewhart cycle)(2) and consists of the following steps: (1) development of a plan to improve a process; (2) testing of the plan; (3) checking of the test results; and (4) implementation or rejection of the plan (Figure 1).

Analytical chemistry is related to QA in two ways: first, analytical methods are used to test and characterize products such as pharmaceuticals, thus giving the customer the assurance that the product conforms with the stated requirements and that conformance is reliable and consistent. The second aspect is that analytical methods themselves have to meet certain quality requirements, so that the results are credible and can be used with confidence for regulatory, economic and research decisions. Since all steps of chemical analysis, from sampling and method selection to choice of equipment and the taking and reporting of measurements, affect the quality of analytical data, confidence in the results can only be achieved...
if the laboratory has the competence and capability to perform the analyses (Figure 2).

This means that all factors leading to the analytical result have to be controlled, clearly described and documented. Furthermore, the analytical result should be linked to the sample and related to RMs or measurement standards by an unbroken chain of traceability. This chain has to be transparent and well documented. Another aim of QA in analytical laboratories is to increase work safety by the use of standardized procedures, regular instrument maintenance, and qualified personnel. Nontechnical aspects of QA cover integrity and independence of the laboratory, which assures that the results are not biased by political, economic or other reasons.

The long-term goal of analytical QA is that the methods and processes that lead to analytical results are globally consistent and accepted. This can be attained by (written) standards and technical specifications. These were traditionally developed for products but can also be used to describe processes, services and systems.

The quality concept has far-reaching implications for trade, e.g. the amount of retesting of products is reduced. With the development of the regional trading blocks such as the European Union (EU) and the North American Free Trade Agreement (NAFTA), efforts have been made to accept standards by mutual agreements and to harmonize standards between the different regions and countries. Certain terms, however, especially those regarding analytical method validation and accreditation, are still used inconsistently in a number of national and international documents. Since most terms relating to analytical QA are defined in English, the possibility exists that ambiguities may be introduced by translation into other languages, a problem which has been dealt with by producing a glossary of analytical terms.

Two elements of QA are necessary in order to assure consistent and reliable analytical results: Internal QA measures comprise elements performed by the laboratory, such as method validation and documentation and the use of RMs; external QA relates to performance evaluation by persons outside the laboratory. Examples of external QA are accreditation by independent bodies or proficiency testing aimed at producing comparable data generated in different laboratories. Accreditation is a system of voluntary peer assessment of laboratory competence conducted by a third party according to national or international standards or guidelines.

## 2 GENERAL ASPECTS AND GOALS

In this section some fundamental terms and concepts of analytical QA are discussed. Since most of the terms, standards and guidelines were developed for laboratories in general, ranging from materials testing to electrical laboratories, an interpretation concerning analytical tasks is necessary. While some aspects of analytical QA, especially regulatory matters, vary in different countries, there...
is a general agreement about the principles of analytical QA. A trend towards international harmonization of the relevant standards and guidelines can be observed. Several books deal with general aspects of analytical QA.\textsuperscript{(5–8)}

### 2.1 Traceability

Traceability is a key concept in QA and is defined in the International Vocabulary of Basic and General Terms in Metrology (VIM)\textsuperscript{(9)} as the “property of the result of a measurement or the value of a standard whereby it can be related, with a stated uncertainty, to stated references, usually national or international standards, through an unbroken chain of comparisons.” Measurement traceability is hierarchical and means that an unbroken and demonstrable path of calibration exists which preferably begins with a national or international standard, for example a standard reference material (SRM) of the US National Institute of Standards and Technology (NIST) or a physical fundamental constant, and ends with the sample. The purpose of traceability is that measurements in different laboratories are accurate representations of the measured quantity within the uncertainty of the measurement, which is a prerequisite for the consistency and comparability of the measurements.

The term “traceability” is sometimes used in a slightly different sense and refers to the chain of documentation from the sample to the result, which is needed in order to repeat the analysis. For this audit trail, the term “trackability”\textsuperscript{(10)} has been proposed.

An example from physical metrology is the calibration chain which links a yardstick to the definition of the meter in terms of the path traveled by light during a time interval of 1/299,792,458 s. By analogy, quantitative chemical measurements should in principle be traceable to the mole, which is the basic quantity in the international measurement system of units [Système International (SI)]\textsuperscript{(11)} for the amount of a defined substance (Table 1).

In order to prove the accuracy of the measurements, laboratories obtain certified reference materials (CRMs). In an ideal case the certified value is directly traceable to the fundamental units of measurement (mass, length, time, etc.) through the use of a primary method such as coulometry, titrimetry, gravimetry or isotope dilution mass spectrometry (IDMS).\textsuperscript{(12,13)} These methods are fully understood, give results with a small degree of uncertainty and do not rely on empirical determination of the measurement function by calibration. In practice, however, applicability of primary methods is very limited owing to the small number of these available.

Buffer solutions made from or traceable to primary standards can be used for the determination of the pH value. A national metrology institute uses a primary standard measurement device to certify primary standards with a defined uncertainty. Secondary RMs can be derived from these with assigned pH values and an uncertainty which includes the uncertainty of the primary standard. The user of a pH meter who buys the certified calibration buffer solutions can therefore trace his or her pH value measurement to a national standard.\textsuperscript{(14)}

In many cases, a rigorous application of the traceability concept in chemical analysis is not viable, since the measurement step is only one part of the analytical process. The uncertainties of sampling or preconcentration steps are mostly uncalibrated and therefore not directly traceable. Furthermore, for some analytical methods, e.g. sum parameters such as adsorbable organically bound halogens (AOX) or the protein content of a meat sample, accuracy can only be stated relative to a reference method.

The strictness of the implementation of the traceability concept depends on the field and on the required level of accuracy. For most analytical laboratories, a practicable interpretation of traceability is that the accuracy and overall measurement uncertainty of the result have been assessed in a transparent and demonstrable way.\textsuperscript{(15,16)} The aim should be traceability to either matrix-matched RMs or to a generally accepted reference method. If both are lacking, then samples spiked with the analyte provide a restricted possibility to assess accuracy and uncertainty.

### 2.2 Measurement Uncertainty

In chemical analysis, significant sources of uncertainty may arise from poor sampling, incomplete extraction of the analyte, contamination, uncertainty of RMs and matrix effects during the measurement step. An analytical result is therefore never more than an approximate estimation of the true value of the measured quantity, and incomplete without a realistic quantitative statement of its uncertainty, which “characterizes the dispersion of the values that could reasonably be attributed to the measurand” VIM. The uncertainty is needed to determine whether a result can be used for its intended purpose and in order to compare a result with others, regardless of the analytical method used. Uncertainty

must be distinguished from error, which is defined as the difference between an individual result and the true value of the measurand.

An analytical result, e.g. concentration of an analyte, is not measured directly but is estimated using a function \( y = f(x_1, x_2, x, \ldots, x_n) \) of intermediate measurement results \( x_i \). The input estimates \( x_i \) are, for example, instrument responses, calibration parameters or correction factors, all associated with uncertainties which have an effect on the uncertainty of \( y \).

Often the uncertainty of the result is evaluated by taking into account solely the standard deviation of the calibration function or from repeated determinations. In this way, the uncertainty is underestimated because only uncertainty components arising from random effects (repeatability) are considered. The overall analytical uncertainty is often much larger and contains uncertainty components arising from systematic effects, as can be demonstrated by the use of CRMs or inter-laboratory comparisons where between-laboratory reproducibility is estimated.

Various approaches in order to realistically quantify the overall measurement uncertainty can be distinguished:

- the step-by-step approach, which calculates the overall uncertainty of analytical result by taking into account the individual contributions of uncertainty (error propagation);
- the experimental approach, which systematically varies all parameters which show a significant influence on the uncertainty of the result;
- the top-down method, which estimates uncertainties directly using suitable reference samples, established reference methods or interlaboratory comparisons in order to determine reproducibility and laboratory bias;\(^{(17)}\)
- other methods based on numerical evaluation of uncertainty components using the bootstrap method, cross-validation or other resampling statistical methods,\(^{(18)}\) or sensitivity analysis using simulations.

In order to achieve consistent and realistic expressions of measurement uncertainty, the ISO Guide to the Expression of Uncertainty in Measurement\(^{(19)}\) has been prepared by several organizations. The ISO Guide describes the step-by-step approach to measurement uncertainty by assessing the individual components of uncertainty in the various analytical steps and combining them to an uncertainty estimation using an error propagation model of the measurement process. A guidance document for the interpretation of the ISO guide in relation to analytical application which also contains worked examples has been prepared by a EURACHEM working group.\(^{(20)}\)

The following steps must be performed in order to assess the overall uncertainty for analytical measurements:

1. identify and list the steps of the analytical procedure, e.g. sampling, sample preparation and calibration;
2. for each step, identify and list the sources of uncertainty which influence the performance;
3. decide which uncertainty contributions have to be further investigated and which can be neglected;
4. express the determination of the measurand as a functional relationship of input parameters;
5. for each significant contribution of uncertainty, evaluate the contribution to the measurand;
6. if relevant correlations between the individual uncertainty contributions exist, their corresponding covariance has to be taken into account;
7. calculate the combined uncertainties of the target quantity as the square root of the sum of squares of the uncertainties of the individual steps and their relevant covariances;
8. an expanded combined uncertainty can be calculated (for security) by multiplying the combined uncertainty by a coverage factor, mostly 2.

According to this enumeration, the main task is to estimate the individual uncertainty components. Two methods of evaluation of the individual uncertainty components can be distinguished according to the method used for their estimation: type A uncertainty components are evaluated by statistical analysis of a series of observations, while type B uncertainty components are evaluated by other means. Each uncertainty component, regardless of the method of evaluation, can be represented by an estimated standard deviation termed standard uncertainty \( u_i \).

Uncertainty components evaluated by type A can be directly represented by the statistically estimated standard deviation \( s_i \) with the associated degrees of freedom: \( u_i = s_i \). Examples are the standard deviation of a mean of observations or the standard deviation of calibration parameters fitted by the least-squares method.

In type B evaluation, the uncertainty component is represented by a quantity \( u_i \) which uses a hypothetical distribution based on assumptions and available information, such as previously determined data from method validation, data from literature or from specifications by the manufacturer.

The uncertainty evaluated according to type B is treated like a standard deviation and is equivalent to \( u_i \). For example, if a maximum upper \( a_u \) and lower value \( a_l \) for the quantity in question is given, then it can be
approximately assumed that all values (exactly 99.73% for normal distribution) lie in the interval \( a \pm 3 \) standard deviations with \( a = (a_0 - a_1)/2 \) if no other information is given. An approximation of the standard uncertainty would therefore be \( u_i = a/3 \). For simplicity, in the absence of other information, a uniform rectangular or triangular distributions may be assumed in order to compute the standard uncertainty, which leads to a standard uncertainty of \( u_i = a/\sqrt{3} \) and \( u_i = a/\sqrt{6} \) relating to 58 and 65%, respectively, of the area in the interval \( a \pm u \).

The individual standard uncertainties \( u_i \) evaluated either by type A or B are then combined, \( u_c(y) \), according to the law of propagation of uncertainty, resulting in the combined standard uncertainty of the result. The expression for uncorrelated uncertainty components is given by Equation (1):

\[
u^2_c(y) = \sum_{i=1}^{n} \left( \frac{\partial f}{\partial x_i} \right)^2 u^2(x_i)
\]

The uncertainties of additive or subtractive corrections or correction factors have to be included in the assessment according to Equation (1). The combined standard uncertainty resulting from uncorrelated individual uncertainty components always exceeds the uncertainty of the individual contributions.

If some variables are not independent of each other, i.e. significant correlations between the variables exist, then the result may be underestimated for a positive correlation, since the contribution terms reinforce each other, or overestimated for a negative correlation, since the contribution terms partially cancel each other out. Therefore, for correlated uncertainty contributions an additional covariance term has to be included.\(^{(19,20)}\)

The probability distribution of the measurand and its combined standard uncertainty is often approximately normal (due to the Central Limit Theorem, which states that even if the original population is not normally distributed, the sampling distribution of means will increasingly approximate a normal distribution as sample size increases). In this the level of confidence is approximately 68% that the measurand \( y \) lies in the interval \( y - u_c(y) \leq y \leq y + u_c(y) \) given a negligible uncertainty of the determination of \( u_c(y) \) itself.

For additional safety, e.g. in industrial applications, the combined uncertainty may be multiplied by a coverage factor \( k \) to give the expanded uncertainty \( U = ku_c(y) \), where \( k \) is usually in the range 2–3, relating to a level of confidence from approximately 95% to approximately 99% for a normal distributed measurand. Generally \( k = 2 \) is used; the exact value for \( k \) has to be stated.

Figure 3 shows typical steps of a spectrometric, e.g. inductively coupled plasma optical emission spectrometry (ICP-OES) or atomic absorption spectrometry (AAS), determination of a solid sample after sample digestion together with the uncertainty contributions.

If suitable RMs are available, the top-down approach which directly estimates the combined uncertainty is in

---

**Figure 3** Typical steps and sources of uncertainty of a spectrometric determination of a solid sample after digestion.
many cases more suitable to assess the uncertainty of the result, since the combined effect of several sources of uncertainty is taken into account in one step. The remaining uncertainty components are the uncertainty of the assigned value of the RM, the reproducibility of the measurements made on the RM, matrix effects due to difference in the composition between sample and RM and steps that are not accounted for, e.g., sample inhomogeneity and sample storage.

In chemical analysis, expert judgement is often required to assess uncertainty components. For example, subjective assumptions on the type of matrix of a sample are often necessary. The EURACHEM guidance document states that “The evaluation of uncertainty is neither a routine task nor a purely mathematical one; it depends on detailed knowledge of the nature of the measurand and of the measurement method and procedure.”

2.3 Statistical Process Control and Control Samples

Statistical process control (SPC) is a means of detecting and controlling unaccounted sources of uncertainty in the analytical process. A process is a structured order of activities and events necessary to reach a certain goal, e.g., a production process or analytical process. A stable process is predictable and shows only small random variations from the average, which can be attributed to factors such as unavoidable random variations of temperature or contamination. The stability of the process is disturbed by assignable causes (also called special causes), which are unnatural variations of the process, resulting, for example, from problems with instruments and reagents or human mistakes. The aim is to achieve and maintain a stable process, since this leads to more reliable results and to less work with adjusting the process.

SPC monitors the process in order to differentiate systematic deviations of the process from the natural random variations and assists in the decision if it is necessary to intervene in order to reduce variability and to maintain the stability of a process. Statistical assumptions are used to help determine whether a variation is solely by chance or due to an assignable cause. Reference works dealing with SPC are those by Grant and Leavenworth and Montgomery.

A process can be visually represented by QC charts, which were at first introduced by Shewhart for the SPC of production processes. A number of variables which characterize product quality are monitored by measuring samples of a certain size extracted from the production process. A graph of the individual variable or some sample statistics, e.g., mean or standard deviation, is then plotted over time or sampling sequence to reflect the course of the process. A control chart usually consists of a central line together with warning and control limits which are based on statistical parameters estimated from earlier samples. Depending on the type of control chart, significant deviations from the target specifications or excessive variability around target specifications can be detected. Control charts can be used to document the process history. Two process characteristics which are of special interest are the location of the mean of the process and the variation of the process.

In contrast to industrial product QC for analytical chemistry, special control samples have to be monitored in order to use control charts. Materials or solutions used for QC must be available in sufficient amounts, stable under defined storage and handling conditions for several months, and homogeneous. The following types of control samples are frequently used:

- standard samples which are solutions of a substance or materials with known purity and concentration without the sample matrix;
- blank samples which are free from analyte and are processed in the same way as the sample in order to evaluate and control contamination from reagents and environment;
- real samples which have the same matrix as the sample but contain an unknown amount of analyte;
- spiked real samples spiked with a known amount of the analyte (if possible of the same chemical species) and forming the basis of recovery experiments;
- matrix-matched synthetic samples which are calibration samples with additional substances contained in the sample matrix;
- CRMs which are real or synthetic samples for which a conventional true value with known uncertainty has been certified by a defined and reliable procedure, e.g., a round-robin test.

Table 2 shows which performance characteristics can be controlled with the different types of control samples. Additionally, instrumental or calibration parameters can be monitored by SPC, such as the temperature of a refrigerator or the slope of the calibration line.

The control samples have to be analyzed at regular intervals, which depend on the reliability of the method and the level of confidence required.

In most cases, analytical applications control charts are used which require quantitative variables. Generally a normal distribution is assumed. Control charts for qualitative attributes also exist but are rarely used. Qualitative attributes follow discrete distributions, e.g., binomial or Poisson distributions. The simplest chart is the individual chart (x-chart) where the individual observations are plotted in the sequence of observation. The course of the plot displays both variation and location...
of the process. Figure 4 shows an \( \bar{x} \)-chart (x-bar chart) which is used to track the location of mean values \( \bar{x} \) of samples of size \( n \). The central line is given by the overall mean \( \bar{\bar{x}} \), usually calculated from stable periods of the process history. The lower control limit (LCL) and upper control limit (UCL) can be expressed by Equations (2) and (3):

\[
UCL = \mu + 3\sigma_x \\
LCL = \mu - 3\sigma_x
\]

where \( \mu \) is estimated by the mean value \( \bar{x} \) and \( \sigma_x \) is the standard deviation of the mean, \( \sigma_x = \sigma/\sqrt{n} \), which can be estimated according to Table 3 using the mean standard deviation \( \bar{s} \). Given a stable process with only random variations and normal distributed data, approximately 99.7% of the sample means are expected to fall inside the 3\( \sigma \) interval. The probability of error is thus \( p \approx 0.3\% \). With a decrease in the factor the sensitivity and the risk of giving false alarm (type I error) increases.

For increased sensitivity of the \( \bar{x} \)-chart warning lines are often added using 2\( \sigma \)\( x \) (\( p \approx 0.05 \)). Other multiples of \( \sigma_x \) can be calculated to obtain limits with specified \( p \)-values.\(^{24} \)

As stated previously, applications of the \( \bar{x} \)-chart in analytical QC require samples with known concentrations, e.g. reference samples, in order to control accuracy. The blank chart often used in trace analysis is an \( \bar{x} \)-chart where the mean values of the blank determinations are controlled to detect changes and trends of blanks. Another application is the recovery chart used to control proportional changes in sensitivity due to matrix components. The basis is the percentage recovery rate [Equation 4]:

\[
RR = \frac{x_{\text{spiked, meas}} - x_0}{x_{\text{spiked}}} \times 100\%
\]

where \( x_{\text{spiked, meas}} \) is the concentration of analyte measured in the spiked sample, \( x_0 \) is the concentration of analyte measured in the sample prior to the spiking procedure.

and \( x_{\text{spiked}} \) is the concentration of analyte added (added value, not determined by method).

Homogeneity of the variances over time is a prerequisite for a reliable use of the \( \bar{x} \)-chart. Changes in precision can be controlled by tracking the range (\( R \)-chart) or the standard deviation (\( s \)-chart). Since the number of replicate determinations in the analytical laboratory is typically \( n = 2 - 3 \), the \( R \)-chart is often used to assess the spread of the measurement values. The range of a sample of measurements is defined according to Equation (5):

\[
R = x_{\text{max}} - x_{\text{min}}
\]  

If the number of samples for each point is higher \( (n > 5) \), the standard deviation can be calculated to assess the spread of data. Range and standard deviation are always positive, a fact which must be considered for the construction of lower limits. These correspond to higher precision and can be used to find causes which lead to the improvement of precision or to detect fraud, e.g. by using identical values instead of replicates.

A combination of the \( \bar{x} \)-chart with the \( s \)- or \( r \)-chart using the same data is especially useful in order to monitor precision and trueness simultaneously. A decision can be made if the variability between the subsets is smaller or greater than that in the subset. The cause of out-of-control situations can be better detected. Out-of-control results differ in a statistically significant way from measurements which were taken in order to establish the control limits, but this does not necessarily mean that the results are useless for the customer. Therefore, in addition to control and warning limits, specification limits can be established, e.g. the measurement uncertainty of a RM.

The construction of the \( \bar{x} \)-, \( R \)- and \( s \)-charts is shown in Table 3. The values \( c_2 \), \( d_2 \) and \( d_3 \) are functions of the sample size \( n \) tabulated in Table 4 and characterize the distribution of the standard deviation and the range.

When the laboratory works at a level of high quality with previously validated methods, the process is stable. This means that the process meets the performance criteria determined during the validation, shows only random deviations and independence between successive points (no trends) and only rarely exceeds the specified limits. On the other hand, a process which displays trends or exceeds the established limits because of an assignable cause, is defined as being out of control. Appropriate measures can then be taken in order to find the cause of the variation and bring the process back to stability. This can mean instrument maintenance, new reagents or even revalidation of the procedure.

A number of tests based on statistical assumptions exist to decide objectively if a process is out of control. For example, a systematic deviation of the mean value can be assumed if a certain number of points consecutively fall below or above the central line. The probability that this is solely by chance is \( P = 0.5 \) for each point, so that \( P = 0.0312 \) \((3.12\%)\) for five consecutive points lying on one side of the central line. Similar assumptions exist for identifying trends from a number of consecutively increasing or decreasing values. Various rules for chart interpretation exist. Some examples which indicate problems with the process are one value outside the \( 3\sigma \) control limits, two of three consecutive values outside of the \( 2\sigma \) warning limits, six values consecutively increasing or decreasing and eight values on one side of the central line and also every unusual pattern (see Figure 5).

Prior to using the charts two cycles have to be completed, which are usually part of the validation of an analytical method. In the first cycle, the statistical parameters of the process are assessed. It is important to investigate these data thoroughly, e.g. using histograms or \( P-P \) plots. Realistic limits for the control chart can only be estimated if all possible variations have been included, e.g. temperature variations and different analysts. For example, establishing meaningful warning and control limits for the \( \bar{x} \)-chart requires that the mean scatters symmetrically around the central line and no trend can be observed. A validation cycle should be used to check these limits. If an unexpected number of out-of-control situations is observed, the limits have to be redefined.

Another chart often used in analytical QC is the Cusum chart, which gives information on small shifts and trends often observed due to ageing of instrument parts or stock solutions and changes of environmental conditions, e.g. temperature. The cumulative sum (Cusum) is calculated accordingly to Equation (6):

\[
\text{Cusum} = \sum_{i=1}^{t} (x_i - \mu_0)
\]

where \( t \) is the time sequence, \( x_i \) are the observations and \( \mu_0 \) is the mean of the undisturbed process, usually estimated

Figure 6 Cusum chart (a) course of measurement values and (b) Cusum chart from these data.

by calculating $\bar{x}$ from the process history. Usually individual observations $x_i$ are used to attain increased sensitivity in comparison with the $\bar{x}$-chart. As long as the only random deviations affect the observations, the Cusum scatters around $\mu_0$. If shifts or trends occur, then the course of the Cusum shows a certain slope (Figure 6a and b).

If the slope exceeds a certain value which is based on statistical assumptions then the process is declared out of control. The limits can be estimated either graphically by using a V-mask or by computation of the slope.

Various process capability indices and operating characteristic curves are described in the literature to assess the performance of control charts. An important characteristic is the average run length (ARL) The ARL is the average number of samples before a value falls falsely outside of the control limit (type I error) and should be high. Figure 7 shows an operation characteristic curve which shows the probability with which a certain shift of the process can be detected for various samples sizes $n$ with the $\bar{x}$-chart using a $3\sigma$ interval.

Other charts which display time series are the moving average (MA) and the exponentially weighted moving average (EWMA) charts. When several process variables are observed which are correlated and thus cannot be controlled independently, there is an increased probability of finding false out of control situations (Type 1 error). In this case multivariate control charts
can be used which are based on principal component analysis, e.g. Hotelling’s $T^2$ statistic.\(^{(26)}\)

### 2.4 Regulatory Aspects and Standards

In order to assure minimal requirements for the quality of analytical results, a number of standards and legal regulations for the analytical sector have been developed. Rules, standards and legislation related to laboratory work form the basis for national and international acceptance of analytical results and for the accreditation of laboratories. The compliance with regulatory and legal requirements varies in different countries and may also depend on the scope of the laboratory, such as first party, representing the vendor or manufacturer, second party, representing the client, or an independent third party laboratory. Generally legal regulations exist for certain branches such as medical and health, pharmaceutical protection and safety, explosives, food and feed related and forensic analyses.

Some standards and guidelines relevant for analytical laboratories are the following: ISO/International Electrotechnical Commission (IEC) Guide 25\(^{(27)}\) (General Requirements for the Competence of Calibration and Testing Laboratories), European Norm (EN) 45001\(^{(28)}\) (General Criteria for the Operation of Testing Laboratories) for laboratories in the EU (will be replaced by the ISO 17025), the ISO 9000 series of standards\(^{(29)}\) addressing quality systems (in the EU the identical EN 29000 series, in the USA ANSI/ISO/ASQC Q9000 series) and the good laboratory practice (GLP) standards and regulations [Organization for Economic Cooperation and Development (OECD) Principles of GLP,\(^{(30)}\)] Environmental Protection Agency (EPA) GLPs\(^{(31,32)}\) and Food and Drug Administration (FDA) GLPs\(^{(33)}\). These standards and guidelines are regularly reviewed and modified.

The technical competence of the laboratory is addressed by the ISO/IEC Guide 25 and the EN 45001, both of which focus on the training and experience of personnel, appropriate equipment, calibration and maintenance procedures, the laboratory organization and the environmental conditions in the laboratory. The new standard ISO 17025 (Table 5)\(^{(34)}\) integrates EN 45001 and will form the basis for worldwide acceptance of analytical results and for the assessment of laboratories by accreditation bodies. Laboratories operating under ISO 17025 have to implement a quality system according to ISO 9001/2. ISO 17025 addresses all kinds of laboratories (except those working in legally regulated sectors such as clinical, safety or pharmaceutical laboratories) including testing, calibration and sampling laboratories.

QUALITY ASSURANCE IN ANALYTICAL CHEMISTRY

These guides and standards only address general requirements of QA for various types of laboratories. Therefore, detailed guidance documents have been prepared by various international or national organizations, e.g. by International Laboratory Accreditation Cooperation (ILAC), which interpret the various standards and guides with regard to the practical application in the analytical laboratory.

The ISO 9000 series of standards, especially ISO 9001 and ISO 9002, address the capability to implement and run a quality system. ISO 9000 defines a quality system as “the organization, structure, responsibilities, procedures, processes and resources for implementing quality management.” The goal is to improve the operational processes of the laboratory in order to minimize human errors. Operational processes relate only to the definition and documentation of operation procedures. The ISO 9000 series (Table 6) does not address the technical competence of the laboratory or the equipment and premises needed to perform analyses.

GLP is a concept covering the organization and conditions under which nonclinical laboratory studies are planned and conducted in order to assess chemicals relating to the safety and protection of humans and the environment. The aim is primarily to prevent fraud, and to assure transparency and clear responsibilities by extensive documentation of studies relating to research and marketing permits of products in fields such as pharmaceuticals, food and feed additives or pesticides. In contrast to the above-mentioned voluntary standards and guidelines, regulations according to GLP are in many countries mandatory for studies in the above mentioned fields such as pharmaceutical, toxicological studies or pesticide residue studies.

The primary aim of GLP documentation can be summarized as documenting ‘who did what and when it was done’. The GLP standards requires a separate quality assurance unit (QAU) which supervises the conformance of the regulations. The requirements concerning facilities and documentation are more comprehensive than those found in EN 45001 or ISO/IEC Guide 25. Owing to the toxicological relevance of the acquired data, GLP also has also stricter rules for the storage and archiving of documents and test items. The development of the GLP Regulations was put forward by the FDA in 1978 following irregularities in toxicological studies. The GLP Regulations were later adopted by the US EPA for pesticide and chemicals metabolism and residue data in the OECD member countries.

3 QUALITY ASSURANCE IN THE ANALYTICAL PROCESS

In order to provide confidence that the analytical result satisfies the stated quality requirements, the laboratory has to take appropriate measures in every step of the analytical process. Prerequisites for developing and using valid analytical methods are appropriate personnel and technical competence. These cover the organizational structure of the laboratory and also instrumentation, maintenance and reagents. With respect to the consistency of the quality measures taken, special attention has to be given to the documentation, which comprises recorded data and laboratory documents. The central document is the quality manual in which the policy of the laboratory and all elements of QA are addressed. This section is primarily orientated towards the requirements of ISO/IEC Guide 25 (ISO 17025).

3.1 Sources and Significance of Errors

Various sources of uncertainty in the analytical process, from sampling to reporting, lead to a certain amount of error (deviation from the true value) of the analytical result. Two components can be attributed to the observed error, namely random error and systematic error.

Random error arises from unpredictable variations of the quantities affecting the analytical result and manifests

itself in the precision of repeated measurements. The random component of error cannot be compensated by correction but can be reduced by computing the mean value of an increasing number of measurements. Often the amount of random error depends on the measured value.

Systematic error remains constant or varies in a predictable way in repeated analyses and leads to inaccurate results. Sources of constant systematic error are, for example, uncorrected reagent blanks, incomplete extraction and inaccurate calibration. Systematic errors may affect the analytical result in different ways (Table 7).

Figure 8 shows the influence of the different types of systematic error on the observed values $x^*$. Systematic errors varying over time can often be attributed to variations of the experimental conditions such as temperature, induced instrument drift or ageing of parts. A reduction of systematic error components can often be achieved by correction by correction of a blank value or a correction factor, e.g. correction of a recovery rate from analyte extraction. Another type of error is spurious error due to human mistakes or instrument failures. Typical examples are confusing the samples, transposing digits in an instrument reading or extreme contaminations of the sample. These errors can be considered as an extreme manifestation of random or systematic error and should usually be eliminated from the data set. Random spurious errors can be detected by statistical outlier tests on replicate measurements. Table 8 shows some examples of possible sources of error in trace analysis, together with the contribution to the analytical result.

Problems with analytical work can, for example, be identified by SPC (section 2.2), staff observations, complaints by customers or internal audits which should be conducted regularly in order to assure that the laboratory work is consistent with the quality system.

PTFE, polytetrafluoroethylene.
include the technical operations and resources of the laboratory. One particular member of the staff should be responsible for ensuring the quality of laboratory operations (part-time or full-time, depending on the size and the resources of the laboratory). A prerequisite for quality in the laboratory work is that the staff members have appropriate competence, training and experience. They should attend external or internal training courses. For unfamiliar analytical tasks appropriate supervision should be available. Records have to be kept, which include information on qualification, additional training and methodological expertise of the staff members. ISO/IEC Guide 25 (ISO 17025) furthermore requires that the laboratory and its staff have to be free from any commercial, financial and other internal and external pressures that may adversely affect the quality of their work.

Procedures have to be established to implement corrective action in an acceptable period when problems with the quality management system or with the technical operations of the laboratory have been identified. This should include an investigation of the cause of the problem. A guideline for performing internal audits is published by the EAL.

### 3.3 Sampling and Sample Preparation

The sampling procedure can strongly affect the analytical result and its uncertainty and depends on the purpose for which the analytical result is to be used. Generally, for analysis, only a small amount, the sample, is drawn at a certain time from the total bulk of material of interest.

Two aspects have to be considered. First, the sample taken must show average properties, spatially and temporally, of the medium being sampled. Spatial resolution presents a problem with heterogeneous or grainy solid materials, temporal resolution is critical for example, in process analysis or environmental analyses of rivers. The second aspect of representativeness addresses the reliability of the determination of the uncertainty of sampling as a measure of the variability of analyte present in a heterogeneous sample volume. The analytical result contains the uncertainties respectively of the standard deviations of all steps (Equation 7):

\[
u_{\text{analysis}} = \sqrt{u_{\text{sampling}}^2 + u_{\text{preparation}}^2 + u_{\text{measurement}}^2 + u_{\text{evaluation}}^2}
\]

(7)

Since sampling uncertainty can be only assessed after preparing and analyzing the samples, analysis of variance in combination with statistical designed experiments or collaborative trials has to be used in order to estimate the sampling uncertainty. The degree of spatial and temporal resolution depends on the problem definition, on the sampling strategy, on the sample mass and on the analytical method. For example, different strategies have to be used in order to determine local or average concentration of a trace contaminant in an alloy. While local contamination can be assessed by analysis of small sample masses, e.g. by laser ablation inductively coupled plasma mass spectrometry (ICPMS), determining average contamination requires higher sample masses, using ICPMS after sample digestion or electrothermal vaporization. In environmental and geological analysis, but also in food analysis, the uncertainty of the sampling step is often the strongest contribution to the overall uncertainty of the analytical result. An example comparing the consequences of different sampling schemes for soil analysis is given in the literature.

Even for homogeneous materials, sampling, sample transport and sample storage can present problems related to sample contamination, loss of analyte or inappropriate sampling procedures. If the sample is not taken by the laboratory then the person who takes it has to be instructed in order to prevent ambiguities, e.g. appropriate sample mass.

The chain of traceability from the primary sample to the sample prepared for analysis has to be fully documented, especially if deviations from the usual protocol occur, in order to assess the representativity of the analytical result of the sample in relation to the medium being sampled. The documentation should include type and source of container, preparation techniques and cleaning procedures if the containers are reused. The interval between sampling and analysis should be as short as possible. Usually samples are stored in a cool, dark place. Prior to analysis the authenticity and the suitability of the sample have to be controlled. The sample has to conform to the sample description, e.g. whether the sample container is sealed.

Analyte loss primarily depends on the nature of the sample and is especially relevant in trace and ultratrace analysis. For example, degradation of organic samples by light or microbiological activity can be reduced by using dark bottles, cooling with ice or stabilizing reagents. Volatile analytes have to be sampled in closed and completely filled containers. Precautions against oxidation must be taken if the aim is chemical speciation. Special attention has to be given to the material of the sample container with respect to:

- short- and long-term resistance against sample, added reagents and, if necessary, pressure and temperature;
- leachability of trace contaminants, filler, lubricant, catalyst;
- sorption/desorption of analytes;
- permeability of organic liquids through the walls of the material;
- cleaning procedures.
It is well known that cations, including iron, copper and lead, are subject to loss due to adsorption and ion exchange, especially on glass surfaces, which is particularly relevant in the sub-micrograms per gram region. This can be minimized by acidification with nitric acid. Silica and sodium can also be leached from glass and contaminate the sample. Polyethylene (PE) or polypropylene (PP) containers contain traces from catalysts, e.g. aluminum, titanium and others, which can be leached. Containers made from fluorinated polymers such as PTFE are to be preferred. Liquid organic samples have to be compatible with plastic material. Volatile organic compounds may migrate into the walls of plastic containers or may leach substances such as phthalate esters used as plasticizers. Glass containers or containers made from fluorinated polymers are therefore preferred for samples such as volatile organic substances, oil and grease. If plastic caps have to be used, they have to be PTFE lined.

Every sample container has to be labeled in order to achieve unique identification. Sample records should contain the unique sample identification, date, time, analytes or methods, added preservatives, potential hazards, location and the name of the person who took the sample. To assure legible and complete information, preprinted labels should be used.

Contamination can be controlled by analyzing blank samples. The inclusion of a sample container blank may be adequate. If the sample blank exceeds the specified limit then appropriate measures have to be taken. For inorganic trace analysis these may comprise high-purity reagents, metal-free tools, and the use of glove-boxes, clean benches or clean rooms. Analyte loss can be controlled by using spiked samples at varying stages of the sample preparation and by calculation of the recovery rate (Equation 4). The quantity added should be based on the typical values found in the sample. A prerequisite for realistic assessment of recovery rates is that the spiked analyte is of the same chemical species (oxidation state, binding state) as that in the sample.

Sample preparation covers methods such as filtration, centrifugation, extraction methods, purging and trapping, microcolumns, digestion methods and grinding dependent on the type of sample. Problems mainly arise from contamination by reagents, especially acids and solvents, and the environment, e.g. dust, and loss of analyte.

### 3.4 Reagents and Standards

Various grades of analytical reagents exist, ranging from technical grade to ultrapure grade depending on the specifications of the supplier. Often the method specifies the required grade; if this is not the case, usually analytical-grade reagents are used. Special attention has to be given to the purity of the reagents and solvents, which is of utmost importance in high-performance liquid chromatography (HPLC), ICPOES and ICPMS and electrochemical methods. Depending on the purpose, water or acids may have to be further purified, e.g. by sub-boiling distillation. Solvents and solid reagents often have to be dried prior to use.

Supplied chemicals should be marked with the date of arrival and the date of opening in order to control the shelf-life. Information on potential hazards, restrictions of use and reagent disposal must be available. Storage conditions depend on the chemicals, acids and volatile solvents should be stored under hoods or in ventilated cabinets. Organic reagents should generally be stored in cool, dark places. In order to reduce deterioration of the initial grade of the reagent by contamination, spatulas, pipets and other tools should never be used directly in reagent bottles. Instead, an approximate amount of the reagent is dispensed into a clean vessel. If reagent is left over it is never returned to the reagent bottle. For acids, solvents and other liquids, bottle-top dispensers made from fluorinated polymers are ideal for dispensing defined volumes directly from the reagent bottle without risk of contamination. Standard solutions and other laboratory-prepared reagents have to be stored in an appropriate container and labeled, dated and signed. Records should exist describing the preparation of the standard, the source of the reagents and all weight or volume operations. To prevent cross-contamination, standards should not be prepared and stored in the sample preparation or storage areas.

Reagent-grade water is a prerequisite for most analytical work. Since feed water always contains impurities, such as dissolved salts and gases, organic compounds, suspended particles, microorganisms and their toxins, techniques such as distillation, ion exchange, carbon adsorption, reverse osmosis, microporous membrane filtration, and ultrafiltration have been used in order to produce water. As shown in Table 9, with each of these

\(^b\) If vapor pressure of the contaminant differs from that of water.
methods only specific types of contaminants are removed. Therefore, for the production of ultrapure water several methods have to be combined, e.g. reverse osmosis and distillation. Important parameters characterizing the suitability of water for analytical purposes are conductivity, total organic carbon (TOC), dry residue and ultraviolet (UV) absorbance. Cartridge-based systems in particular have to be constantly controlled for possible exhaustion or failure.

3.5 Instruments and Computers

Laboratory equipment can be categorized as consisting of measuring instruments, such as spectrometers, chromatographs, balances, thermometers and timers, volumetric equipment, such as pipets, burets and volumetric flasks, general equipment, such as refrigerators, ovens, stirrers and non-volumetric glassware, and computer equipment including printers, backup systems and network components. The level of maintenance necessary varies from cleaning to regular renewal of wearable parts. Measuring equipment has to be calibrated frequently. The calibration interval ranges from daily, or prior to each use, such as spectrometers or pH meters, to monthly or annual calibration intervals as in the cases of balances and timers. Other equipment which influences the analytical results, such as volumetric glassware, refrigerators and ovens, should be checked regularly.

For major pieces of equipment documentation should exist which includes manufacturer, type, serial number or other unique identification, year of manufacture, operating conditions and installation requirements (environment temperature, cooling water, electricity and gases), modifications (description, when, by whom) and application areas, cleaning, calibration and maintenance procedures and intervals.

Analytical instruments, e.g. spectrometer systems, usually consist of various subsystems. It is therefore necessary to evaluate the equipment consisting of electronics, analytical operations and samples as an integral system. For example, a spectrophotometer system comprises mechanical and optical components, such as light source, monochromator and detector, hardware and software for instrument control, data acquisition, data evaluation and printing or displaying the measurements. The system should therefore be tested using control samples with concentrations over the whole specified range. Test criteria for a spectrophotometer are accuracy of wavelengths, signal-to-noise ratio and linearity of the absorbance response. The recorded data, e.g. spectra, are then compared with previously recorded spectra, for example provided by the vendor, regarding peak positions, intensities and relative standard deviation (RSD) of the measured signal. This process is often referred to as operational qualification or system verification. Table 10 shows some parameters for operational qualification or verification for different types of instrumentation. Computer hardware and software components of analytical instruments can also be tested by using stored test data files. These tests are employed to check compatibility after hardware components have been changed or instrument software or operating system updates have been performed. The results of these tests should be automatically documented.

In pharmaceutical analysis, the combination of method, software and hardware validation is referred to as system suitability testing. Appropriate methods are described in several pharmacopeias, e.g. the USP. For example, in order to check if a chromatographic system is suitable to perform a particular analytical task, several parameters, including resolution, repeatability and capacity are determined using a test solution.

Today, laboratories use analytical instruments which rely on computers for control and data acquisition, storage and evaluation. Furthermore, data are stored in databases, e.g. using a laboratory information management system (LIMS), which in many cases are networked. Hardware and software components are the frequent cause of failures, data loss and erroneous results. Since the quality of software and hardware greatly influences the reliability of an analytical method, specific GLP regulations relating to computers and computerized instruments exist. These are the OECD GLP consensus document ‘The Application of the Principles of GLP to Computerized Systems’ and the EPA Good Automated Laboratory Practices (GALPs). The GALPs are applicable for computerized instruments when it is possible for the user to modify the data, defined as LIMS by the EPA. Validation of

computerized analytical instruments is also covered by Huber.\textsuperscript{46}

Software comprises all programs and program systems necessary for controlling the hardware, e.g.

- application software which may be commercially available, such as word processors, databases and spreadsheets, or by the laboratory, such as customized data evaluation procedures;
- system software, such as operating systems, system utilities, compilers and diagnostic software;
- firmware, which is software that is embedded in a hardware device that allows the execution of a program or reading of data but does not allow modification by the user, e.g. system BIOS (basic input output system) or signal processing hardware;
- data files, such as raw and processed data and archives;
- documentation files, such as standard operating procedures (SOPs) and operating manuals.

Hardware and especially software components are subject to frequent modifications. Changes comprise new peripheral devices, new firmware, changes to documentation and modifications of programs and data, etc. Since all components interact, the installation of a new software version may lead to complete loss of data. Therefore, a configuration management system, often termed “change control”, must exist to ensure that changes are only made by authorized staff and followed by adequate tests. The procedure requires documentation of all changes and results of the validation tests. Version numbers have to be accessible to the user. It should always be possible to restore the previous software versions, if problems with new versions occur. Because life cycles of software versions and hardware are limited, special attention has to be given to ensure compatibility with archived data. This can mean that outdated hardware components, e.g. drives or printers, may have to be maintained to access the archives.

Preventive measures have to be taken in order to assure the data safety of computer-based systems. Data loss and damage can occur by human mistakes, software and hardware failures and environmental influence. Therefore, regular backup procedures have to be scheduled. The write-protected backup copies have to be archived in a safe place. In addition, data safety provisions have to be taken against intentional manipulation of the data, a problem which has increased due to networking. While computer software is an immaterial product and not subject to ageing, the media, e.g. disks and tapes, on which software and data reside can deteriorate with time. Usually hard copies (printouts) are archived together with the electronic archives because the task of copying and verifying the electronic copies is time and cost intensive.

Software QA, verification and validation are a field on their own.\textsuperscript{47,48} The ISO/IEC 9126\textsuperscript{49} states six standard basic characteristics of software quality, namely reliability, functionality, usability, efficiency, maintainability and portability. The quality of software algorithms greatly influences analytical results. For example, poor peak integration algorithms may lead to unreliable results if the background noise is high or peaks are not well separated. One approach to software validation is by testing the program with reference data sets, which must be representative for the application. Another approach is to use computer-generated data with known solutions. Reference data sets for statistical software such as regression calculation are provided online, for example, by NIST.\textsuperscript{50} In contrast to these “black box” approaches, i.e. no information about the structure of the program is necessary in order to perform the tests, ‘glass box’ tests assess the structure of the program, e.g. control structures. Often reference software which has been validated by use, due to the number of installations, exists for a problem. In this case the results achieved with the test data have to be compared with the reference software. Simple programs can be verified by investigating all possible input values together with the given output.

3.6 Reporting Results

The results of analytical determinations have to be clearly and unambiguously documented in a test report or certificate. This report has to include the address of the laboratory, identification and description of the samples, date of sample receipt, a short description of sampling and analytical procedures and analytical result with the accompanying uncertainty, and has to be dated and signed. It is important to make clear whether the analytical result relates to the whole sample or a portion, to an extract, to dry or wet sample mass, etc.

To avoid ambiguity when reporting quantitative results, special attention has to be given to the number of digits and to the units. Only significant figures are reported and include a single doubtful digit. The measurement uncertainty has to be considered, which means that the number of digits has to be justified. For example, if the result of an analytical determination is reported as being 20.4 µg L\textsuperscript{-1} then it is expected that the last digit is uncertain. If, on the other hand, the expanded uncertainty is known to be $u_e = 1$ µg L\textsuperscript{-1} then the concentration value should be rounded to 20 µg L\textsuperscript{-1}. Preferably the uncertainty of the result should be included, especially in cases where there is doubt about the number of significant digits because of zeros in the last digits, leading to 20 ± 1 µg L\textsuperscript{-1}. Results relating to a concentration or
content must never be reported as zero. An acceptable way is to report a result as being smaller than a certain limit, e.g. the quantitation limit.

In research and development and also in product conformance testing, the customer is often interested in the opinion of the laboratory in relation to the stated problem. This is usually termed “professional judgment” and comprises opinions, conclusions and interpretations based on the measurements and observations and also on experience, knowledge and other sources of information such as literature. Professional judgement is therefore based on facts and observations but includes a certain level of subjectivity. The judgement should not be biased by political opinions. It depends on the relevant standards and regulations whether professional judgement may be included in the report. A problem is that the ability of the laboratory to perform qualified professional judgment is difficult to assess.

3.7 Documentation and Software

The documentation of a laboratory can be subdivided into three categories: documents contain instructions and guidelines regarding quality measures and operating procedures; records comprise all data which demonstrate the work done; and organizational documents contain data which have to be changed frequently, such as a list of reagents.

The documents are organized hierarchically. The quality manual forms the top of the hierarchy and addresses all relevant topics which influence the quality of the laboratory. The main purpose of the quality manual is to achieve internal transparency, e.g. documentation of responsibilities, and external transparency, e.g. for customers and accreditation bodies, of the work performed. An important point is the description of the scope of the analytical work performed by the laboratory such as analytical methods or fields of work, for which appropriate staff training, facilities and resources have to be accessible. This is needed in order to decide if a contract can be accepted by the laboratory and if the contract contains routine or new work. For accredited laboratories this includes the scope of accreditation.

The contents of a quality manual usually include a quality policy statement by the management, the definition of organizational structure of the laboratory, description of the scope of the analytical work, description of personnel, document control, sample handling, a description of premises, instruments and reagents with references to more detailed documents, internal QC schemes, aspects concerning safety, health and waste disposal, procedures for ensuring traceability of the results, procedures for reporting analytical results, procedures for corrective action following deviations from documented policies or customer complaints, procedures for dealing with subcontractors and procedures executing internal audits. Usually the quality manual contains references to external documents describing the relevant legal requirements, standards and guidelines and internal documents such as a SOP and sample forms of protocols, e.g. for reporting results.

SOPs are formalized documents which describe in detail all routine work repetitively performed in the laboratory relating to analytical methods and instruments but also to procedures such as reporting results, document handling and writing a new SOP. In this way consistency of the work, traceability of the results and aspects regarding work safety, environmental and economical aspects such as waste production and reagent use are documented and well regulated. Furthermore, SOPs help auditors and customers to assess the work done in the laboratory. SOPs usually contain the following information prior to the written procedure: title, author, approved by whom, released by whom, date until valid, revision date, version history.

Systematic document control has to be performed in order to assure that only current versions of the documents are used and that revised documents are properly archived for future access. This consists of measures for approval, release, modification, drawback, identification, indexing, storage, retrieval and distribution of documents. All relevant documents and records have to be accessible for a defined time in order to allow historical reconstruction of analytical work.

Reports and certificates containing the results have to be clearly written and laid out in order to prevent misuse or misunderstanding by the customer. If ambiguous terms are used, e.g. limit of detection, then reference to the definition should be included. Amendments should be not made in the report but as a separate or a new document which supersedes the old one.

For laboratories working under GLP, archiving is mandatory for all documents, raw data, which are data necessary to repeat the data evaluation, protocols, specimens and reports. For example, the German adaptation of the GLP requires that raw data and other records have to be stored for a period of 30 years. For other laboratories it is advisable to keep records such as sampling records, raw data from calibrations and measurements, calculations for processing the data, calibration records, records from SPC, analytical results and certificates, staff records and records from audits for some years, so that the long-term performance of the laboratory can be assessed and possible problems can be identified retrospectively. Records should always be signed and dated, and possible confidentiality, especially of analytical results, has to be preserved. Archived records have to be protected from deterioration and loss.
Paper documentation is increasingly being replaced by data processing. With the advent of laboratory automation and computer networks, specialized database systems were introduced in the laboratory. These LIMS model the sample flow of the laboratory (Figure 9)\(^5\) and fully document the “life cycle” of a sample. Typical tasks of a LIMS comprise registration and labeling of samples, entering results, generating reports, management and version control of documents such as SOPs and management of instrument calibration and maintenance data. Furthermore, often, data such as customer addresses or accounting data are processed and stored, which may lead to additional requirements regarding the confidentiality of these data. Advantages of electronic over paper documentation are that consistency, completeness and access of the data can be controlled. Depending on the authorization of the user of the LIMS, different access levels are possible, while simultaneous access by different users is possible. In many cases an audit-trail function records all actions performed by the user. Today most LIMS use client–server architecture using an SQL (structured query language) database server which can be accessed simultaneously by several workstations in order to query, modify or complete the data sets.

**Figure 9** Information flow in a LIMS.

### 4 METHOD DEVELOPMENT AND VALIDATION

In order to demonstrate that an analytical method is suitable for the required purpose, the method has to be validated. An important aim is to determine systematically certain performance characteristics of the analytical method, e.g. limit of detection or linearity, in order to demonstrate the technical capabilities of the method. The ISO definition states that validation is “confirmation by examination and provision of objective evidence that the particular requirements for a specific intended use are fulfilled” (ISO 8402).\(^1\) A prerequisite for method validation is that the equipment used has to be checked and clearly described.

The amount and type of validation data depend on the intended purpose of the method. Newly developed methods always have to be validated to some extent. If the method has been developed especially for a certain customer then the degree of validation will be lower than for methods which are to be used routinely. Even well-established standard and official methods need to be validated to a certain degree when performed with different laboratory equipment and reagents and by different analysts. The highest degree of validation is of course necessary in order to establish new standard or official methods, such as the Association of Official Analytical Chemists (AOAC),\(^5\) EPA or Deutsche Institut für Normung (DIN) methods. In this case interlaboratory studies are mandatory. Furthermore, the degree of validation depends on the consequences of an erroneous result. As ISO Guide 25 states: “Validation is always a balance between costs, risks and technical possibilities”.\(^2\) Therefore, comprehensive method validation is mandatory in pharmaceutical analysis. Minimum criteria and requirements of the analytical method should be listed before the method is developed and validated.

Various validation strategies and procedures are described in the literature.\(^5,54–58\) Terms are often not used consistently, but the procedures and parameters discussed are generally identical. Therefore, it should always be stated which convention has been used, e.g. for reporting the limit of detection. Certain validation procedures may be required by regulations, e.g. in the pharmaceutical sector. Performance characteristics typically assessed are precision, accuracy, linearity, working range, specificity/selectivity, limits of detection and quantitation and robustness/ruggedness of the method. The final step of the validation procedure is a written documentation of the method SOP, which contains the validation data. The validation data also form the basis for SPC measures.

Some possible approaches to method validation are as follows:

- **Validation using RMs**, which is the most common approach for intra-laboratory method validation. The reliability of the validation procedure depends on the quality of the RM. If no RM is available, spiked samples can be used, with limitations.

- **Comparison with another analytical method**. The results obtained using the analytical method to be validated are compared with a reliable, previously validated method.

- **Comparison with other laboratories** by a collaborative study.\(^59\) Parameters which can be obtained include uncertainty, ruggedness and reproducibility,
while systematic deviations cannot be assessed. In many cases the use of collaborative studies for method validation is impractical because the intended scope of the method is narrow or, as is often the case in pharmaceutical analyses, the samples must not be made available to competitors.

**4.1 Calibration and Recovery Studies**

With a few exceptions, e.g. titrimetry, analytical methods require adequate calibration. In this case the calibration forms the basis of the method validation. The most common model is the linear model with the functional relationship in Equation (8):

\[ \hat{y} = a + bx + \epsilon \]  

(8)

fitted by least-squares regression, where \( \hat{y} \) is the estimated measurement value depending on the concentration or content \( x \) of the calibration sample, \( b \) is the slope of the calibration function and \( a \) equals the blank value, e.g. from solvents or reagents. The model deviations (residuals) are \( \epsilon = \hat{y} - y \). If the blank value obtained from the calibration sample and from the sample which is to be analyzed differ significantly from each other, it has to be corrected for. Assumptions for using the model according to Equation (8) are (1) a linear relationship or one that can be linearized by transformation, (2) the concentration error of the calibration standards is negligible compared with the measurement error, (3) the measurement errors follow a normal distribution, (4) homogeneity of the variances, which means that the precision of repeated measurement remains constant over the working range. If deviations from assumption (1) are observed, either the working range has to be reduced or a nonlinear model has to be used. If assumption (2) is violated severely, e.g. \( s_x \approx s_y \), then error-in-variables regression models may be used.\(^{60}\) Violation of assumption (3) is usually unimportant except in severe cases where outliers are observed, e.g. problems with the instrument. Outliers have to be eliminated prior to estimation of the regression parameters, preferably by using statistical methodology. For asymmetric distributions transformations can be used. The assumption of homogeneity of variances often does not apply, and most methods, e.g. ICPOES, show an increase in absolute signal variance with increasing concentration while the RSD \( (s/\bar{x}) \) usually decreases or remains constant. Reduction of the working range or taking into account of the functional relationship between concentration and standard deviation of the observed signal by using weighted regression may be appropriate.

Recovery studies are performed in order to assess signal depression or increase which is caused, for example, by incomplete analyte preconcentration or extraction steps or matrix effects. Real samples are spiked with increasing amounts of analyte and analyzed before and after each spiking procedure. The sample must be homogenized and the added analyte should be of the same species as the analyte to be determined. The recovery can then be calculated according to Equation (4). The recovery function (Figure 9) can be determined by regression of the added versus found values. Ideally, the recovery function has a slope of 1 and an intercept at the origin. If the deviation from the ideal relationship is due to influences of the sample matrix significantly (relationship \( x^* = bx \) in Figure 9) then either matrix-matched calibration samples or the standard addition method have to be used.

**4.2 Performance Characteristics**

Table 11\(^{61}\) shows which performance characteristics have to be assessed for different purposes. For qualitative parameters, e.g. substance identification, it has to be assured that other substances do not interfere. Also, the lower limiting concentration for positive identification has to be assessed. Quantitative methods are usually based on some kind of calibration curve. Relevant parameters are range, linearity, precision and accuracy of the method. Both qualitative and quantitative determinations are affected by small variations of the experimental conditions to a certain extent, which determine the robustness/ruggedness of the method.

The scope of the validation is determined by the range and the types of matrices covered by the procedure. The determination of a physico-chemical parameter, e.g. temperature or mass, is of a much broader scope than an analytical method combining several steps. If an analytical problem is outside the scope of the validation, e.g. because of a different sample matrix, then the method has to be revalidated in order to show that the reliability is not affected.

4.2.1 Precision

Precision of a method is determined by replicate analyses of a homogeneous material. Usually 10 replicates are measured. The replicates have to be independent to assess realistically the precision of the method, which means that the samples have been independently prepared. Precision is generally expressed as absolute or relative standard deviation of the measurements. If the calibration indicates nonhomogeneity of variances, then several replicates (about 3–5) have to be measured for different concentrations. The quantitative assessment of precision depends on the measuring conditions: the lowest variability is expected if the replicates are prepared and analyzed within a short period of time by the same analyst using the same equipment. The repeatability standard deviation, \( s_r \), is an important parameter for SPC. Higher variability is observed if subsamples of the same homogeneous sample are analyzed by different analysts in different laboratories using different equipment and reagents. This so-called reproducibility standard deviation, \( s_R \), is a realistic assessment of the long-term precision of the method. The term intermediate precision\(^\text{27}\) describes the within-laboratory precision achieved by different analysts on different days using different equipment and reagents, and usually lies between repeatability and reproducibility. For qualitative measurements, precision can be interpreted as the percentage of false (positive or negative) identifications.

4.2.2 Accuracy

Accuracy is defined as the closeness of agreement between the means of measurement results and the accepted reference value for the sample (ISO 3534-1).\(^\text{62}\) (Note: for a set of values, ISO defines accuracy as a qualitative concept combining bias and precision. Trueness relates to closeness of agreement of the average result of a large number of determinations.) For many analytical methods accuracy is strongly affected by the matrix composition and interferences. Accuracy can be determined (1) by analyzing samples with defined and known analyte concentration with identical or very similar matrix composition, as a matter of preference using CRMs, (2) by using a reference method of known accuracy and (3) by recovery experiments using samples or blank matrices spiked with the analyte. Because of the lack of suitable RMs and methods, the third method is often performed. In many cases recovery studies are problematic since the species of the added analyte may differ from that in the sample. This is especially true for solid samples such as food, geological samples or material where a realistic assessment of accuracy requires RMs or methods. Accuracy cannot be deduced from interlaboratory comparisons.

4.2.3 Working Range

A reliable application of quantitative methods is possible only in a certain range of analyte concentrations between the limit of quantitation and an upper limit which depends on the measuring principle and technical aspects. This working range relates to the concentration in the measuring samples following all sample preparation steps and not to the primary samples. In many cases a range of linear response exists where a proportional relationship between signal and e.g. analyte concentration can be observed. Often a linear response can be achieved by mathematical transformation of the signals, e.g. by Beer’s law. Linearity can be assessed by visual inspection of the residual concentrations \( c - \hat{c} \) between the measured concentration and the concentration calculated using the regression model. A prerequisite is that the concentrations, usually \( \geq 5 \) independently prepared samples and a blank, cover the whole linear range. Statistical tests comparing the residuals between different regression models may also be used, while regression statistics such as the correlation coefficient or residual variance can be misleading.\(^\text{63}\) Outliers can be identified by replicate analysis and removed by using appropriate statistical tests. Nonlinear relationships between signal and analyte concentration can also be evaluated, but depending on the function, more calibration samples are needed since more parameters have to be estimated.

4.2.4 Uncertainty

The combined effects of bias, long-term precision and uncertainty due to calibration can be quantified using the measurement uncertainty concept (section 2.2).

4.2.5 Limit of Detection and Quantification

The lower limit of the working range is of special importance in trace analysis. Since the signal-to-noise ratio of the analytical signal decreases with lower concentrations, a concentration range exists where the probability of distinguishing a trace concentration from the blank sample lies below a certain significance level \( P \). Several definitions exist for determining this ‘limit of detection’ or ‘detection limit’\(^\text{64}\) and therefore the method used has to be stated. All approaches are based on assessing the repeatability of measurement near zero concentration either using blank samples or information acquired from the regression function. The most frequently used approach is based on the standard deviation of the sample blank \( s_B \) usually determined from 10 replicate measurements and expressed as Equation (9):

\[
x_{DL} = \frac{k s_B}{b}
\]
where \( b \) is the slope of the calibration function and \( k \) is a factor; usually \( k = 3 \) or 3.3. In chromatography the baseline noise is used to estimate the limit of detection. The limit of detection strongly depends on the sample matrix. Detection limits provided by instrument manufacturers are generally determined using simple matrices, e.g. water, and should therefore be interpreted with caution. More sophisticated definitions use the residual variance of the calibration curve.\(^{(65)}\) Only values near the detection limit should be taken into account, since nonhomogeneity of the variances and even a low degree of nonlinearity can lead to a biased estimation. The lowest concentration of analyte in a specific matrix for which a certain RSD can be specified, is termed “limit of quantification”, “quantitation limit” or “limit of determination”. A value of \( k = 10 \) is often used as a factor which relates to an \( \text{RSD} \approx 10\% \).

### 4.2.6 Selectivity and Specificity

Generally selectivity and specificity both address the fact that interfering substances lead to increased or decreased concentrations determined for the analyte. Both terms are sometimes used with different meanings. Specificity has been defined as “the ability of a method to measure only what it is intended to measure”\(^{(53)}\) and as “the ability to assess unequivocally the analyte in the presence of components which may be expected to be present”,\(^{(57)}\) while selectivity relates to “the extent to which other substances interfere with the determination of a substance according to a given procedure”.\(^{(66)}\) Sometimes selectivity is only used in connection with multicomponent analysis, e.g. in chromatography, while specificity relates to single-component methods, such as AAS.\(^{(24)}\) Selectivity and specificity have to be investigated for both qualitative and quantitative methods. Except in special cases such as atomic spectroscopy, where all interferences may be known, it is almost impossible to state that a method is not affected by interferences or to identify all possible interferences. Since also combinations of noninterfering substances may lead to inference, not all potential interfering substances can be tested. In practice, interferences which are expected to occur are deliberately introduced in the sample, and favorable statistical experimental design is employed. Selectivity can be enhanced by isolation, preconcentration, or clean-up of the analyte in the pre-treatment step, by optimizing instrumental parameters or by using chemometric methods such as peak separation or multivariate calibration in the data evaluation step.

### 4.2.7 Ruggedness

The reliability of an analytical method depends on various environmental parameters and operating conditions which change during normal usage. If the effect of these changes on the accuracy and precision of the method is small then the method behaves ruggedly. The term robustness is used synonymously.\(^{(57)}\) The limits of the parameters where the reliability is not affected have to be assessed and documented. Ruggedness can be determined by two methods:

- by an interlaboratory study (method comparison study), where the influence of different instruments, analysts and reagents can be studied.
- by an intralaboratory study, where small deliberate changes have to be made in a systematic way on all parameters which significantly influence the analytical result.

Preferably, an experimental design based on factorial experiments should be used for varying the influence factors.\(^{(53)}\) For quantitative methods the calibration has to be included in the study.

### 4.3 Reference Materials

An RM is a substance of which one or more properties are sufficiently established to be used for validation, calibration and method comparison. RMs are supplied with a certificate of analysis but must be distinguished from CRMs, “one or more of whose property values are certified by a technically valid procedure, accompanied by or traceable to a certificate or other documentation which is issued by a certifying body” (ISO Guide 30).\(^{(67)}\) The term SRM is also used, e.g. by NIST (Table 12). The certificate usually covers aspects such as form of the material, e.g. powder, intended use of the material, e.g. analytical method, method used for analysis and analyte concentration or content together with an uncertainty statement.

</table>
The properties of RMs and CRMs usually have been determined through interlaboratory testing or definite methods. CRMs have to be certified by following the procedures described in ISO Guide 35. In most cases working standards are derived from the CRM for calibration and SPC. Therefore, for the laboratory a CRM forms a useable end-point of the traceability chain. The general properties of RMs should be the same as for control samples, e.g. stability and homogeneity. CRMs and RMs used in the analytical laboratory relate to chemical composition and trace elements; examples are shown in Table 12.

CRMs and RMs are available from, among others, NIST (US Department of Commerce, NIST, Gaithersburg, MD, USA), BCR (Bureau Communautaire de Référence, Commission of the European Community, Brussels, Belgium), BAM (Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany) and LGC (Laboratory of the Government Chemist, Teddington, Middlesex, UK). Data bases on RMs/CRMs are the ISO Directory of CRMs and COMAR (International Data Bank on RMs, Central Secretariat of COMAR, Laboratoire National d’Essais, Paris).

5 EXTERNAL QUALITY ASSURANCE

5.1 Proficiency Testing

Various types of inter-laboratory comparisons exist, which are performed for investigation the properties of methods, to characterize a material or to compare laboratories. When laboratory performance is investigated by a third party, the comparison is termed a proficiency test. The purpose is then to demonstrate the capability of the laboratory to perform a certain type of analysis using an established method with known properties. Special attention has to be given to the homogeneity and stability of the sample which is distributed.

Procedures for proficiency testing are described in ISO Guide 43, ‘Proficiency Testing by Laboratory Inter-comparisons’. Criteria for evaluating the laboratory performance are accuracy and precision of the results. The most commonly chosen approach(69) is to calculate the standardized $z$-values according to Equation (10):

$$z_i = \frac{|x_i - \mu|}{s}$$ (10)

where $x_i$ is the analytical result from the laboratory $i$, $\mu$ is the true or accepted reference value and $s$ is the standard deviation calculated from the results from all laboratories. Prior to computing the standard deviation, outliers must be identified and eliminated. Another prerequisite is approximate normal distribution of the data.

The $z$-values are interpreted as follows:

- $z \leq 2$ acceptable
- $2 < z < 3$ questionable
- $z \geq 3$ not acceptable

The interpretation of the $z$-values is based on the confidence regions of approximately 95% and 99%. Proficiency tests should be used for learning and correction rather than judgment to increase acceptance. (70)

5.2 Accreditation

ISO/IEC Guide 2 defines accreditation as a “procedure by which an authoritative body gives formal recognition that a body or person is competent to carry out specific tasks” (71). The laboratory can thus demonstrate its competence in certain fields by conforming to international or national standards. Typically following steps can be distinguished in an accreditation procedure: application, assessment, accreditation and surveillance. Laboratories applying for accreditation have to fulfill certain requirements according to national or international standards with the scope of accreditation ranging from a specific test method to an entire field of testing. The guides and standards most widely used for laboratory accreditation are ISO Guide 25 (soon ISO 17025) and in Europe EN 45001. In future the ISO 17025 will further improve internationally standardization of laboratory accreditation standards. Various programs for accreditation exist in different countries; an overview is given in an ILAC publication. (72) In Europe where an important aspect of laboratory accreditation is the reduction of trade barriers most accreditation bodies are governmental organizations whereas in the USA various programs are run by different levels of government and the private sector. These are in some cases state and industry specific and often use their own terminology, e.g. designated, inspected, accepted or nationally recognized laboratory. Breitenberg(73) gives six reasons for a laboratory to participate in an accreditation program:

- outside check of its internal quality program;
- proof of competence to higher level management within the organization;
- competitive advantage over other unaccredited laboratories;
- a means of protection in liability proceedings;
- a means of established credibility within the public;
- contracts or procurement requirements.

Accreditation does not imply that the results of the laboratory are generally better than those from laboratories that have not taken part in an accreditation program, but it demonstrates the laboratory’s capability to perform certain tasks.

Spectroscopic calibration is the process of using mathematical calculations to relate the measured spectroscopic properties of a set of samples to the chemical composition (and sometimes other properties) of those samples. Any of several algorithms are employed to perform these calculations. Regardless of the algorithms used, however, successful execution of this process depends on properly performing several tasks before and after the main calibration algorithm is applied: selecting a suitable set of calibration samples to “train” the system, using the correct algorithm to match the characteristics of the measured data, and properly evaluating and validating the calibration model developed. In this article, these various aspects of calibrating spectroscopic instruments to perform quantitative analysis are discussed. The article ends with an overview of the various algorithms that are available to perform the calibration process.

1 INTRODUCTION

“Calibration” means different things to different people. The definition in one widely accepted dictionary is “to determine, rectify, or mark the graduations of”. This definition is fairly specific: it is intended to be applied to devices such as thermometers. A more general, and perhaps more generic, meaning might be “to make readings (presumably from an instrument or some other measurement device) conform to those of a standard”. This definition, while more generally applicable, has problems of its own (which readings?, what standard?, etc.) but, even if those problems were solved, it would not even begin to address the meaning of “calibration” as used in modern spectroscopic practice. Some time ago, I started to discuss the question of calibrating a spectrometer with a well-known, highly regarded spectroscopist. It took some time to realize that we were talking at cross-purposes, since his definition of calibration was essentially “to ensure the accuracy of the wavelength scale of the spectrometer”, which had nothing to do with the points I was trying to make. Other meanings, which are certainly reasonable and justifiable in appropriate spectroscopic contexts, are: to ensure accuracy of the transmittance scale, or of radiant energy measurement, but these meanings also have nothing to do with “calibration” as used in the current terminology.

What, then, do we mean by the term “spectroscopic calibration”? The definition given in one recent book about chemometrics is “the process of constructing a model that is used to predict characteristics or properties of unknown samples”, and this is pretty close. In this discussion, at least, the meaning ascribed to the term “spectroscopic calibration” is the use of mathematical algorithms to relate spectroscopically measured quantities to the chemical composition (and sometimes other properties) of samples; Beebe’s definition can be expanded slightly since the models may or may not ever be used to make actual predictions. The most common use of the term is to express the percentage of various chemical constituents, although sometimes the interest is in the cumulative effect of the components (e.g. the octane rating of gasoline), or a physical property (e.g. viscosity), or an operational parameter (e.g. heat content of fuel). It is often desired, and usually possible, to calibrate a set of samples for more than one constituent or property. This is advantageous, because when performing routine analysis on the actual “real” samples of interest, it then becomes possible to analyze those samples for all of the constituents and properties for which
calibration models exist, from a single measurement of the spectrum.

Modern spectroscopic practice has progressed far beyond the simple use of Beer’s law to relate the absorbance of an analyte at a characteristic wavelength to the concentration of that analyte. Although Beer’s law has not failed us, and indeed is still the basis of the methods we use, as described in at least one book, a simple measurement of absorbance is not sufficient to accommodate the variety of conditions encountered when using spectroscopic measurements to perform “real-world” analysis.

To allow accurate analysis in the face of electronic and other forms of noise, inhomogeneous samples, and a plethora of other phenomena that can affect spectroscopic readings, a variety of sophisticated mathematical techniques has been developed that attempt (with varying degrees of success) to extract the analytical information from the spectroscopic data. It is the application of these techniques that define the modern meaning of the verb “to calibrate”.

Note, however, that the term “spectroscopic calibration” also has a related meaning as a noun: it is the collective set of mathematical parameters resulting from the application of the calibration process to a set of data. This is also sometimes called the “mathematical model”, or the “calibration model”, but the simpler term “calibration” is often used on its own.

1.1 Why Calibration?

As indicated above, Beer’s law still works and can be applied in those measurement situations that are simple enough for it to continue to apply. If the samples to be measured are clear solutions, if the solvent has no absorbance at the wavelength of analytical importance, if the analyte of interest has absorbance bands, if those absorbance bands are not interfered with by bands of the solvent or of other components of the sample, if the analyte does not interact (chemically) with either the solvent, other components of the sample, or itself as the concentration changes, if the samples are stable with time, if the spectrometer is sufficiently noise free and linear in its response to the radiant energy, then we can perform the following experiment:

1. Measure the radiant energy through the system at an appropriate wavelength in the absence of a sample (call this $I_0$).
2. Measure the radiant energy through the system at the same wavelength with the sample present in known thickness (call this $I$).
3. Calculate $T$ (transmittance) as $I/I_0$.
4. Calculate $A$ (absorbance) as $\log_{10}(1/T)$.
5. Calculate $\varepsilon$ (the absorptivity) from the formula (Equation 1):

$$A = \varepsilon bc$$

where $b$ is the thickness of the sample and $c$ is the concentration of the analyte.
6. Measure the absorbance of other samples and calculate the concentration from the measured absorbance and the (now known) values of $\varepsilon$ and $b$.

Steps 1–6 essentially constitute the classical, standard, Beer’s law approach to analysis; indeed, this in itself is a limited, specific type of calibration. But it involves a lot of “ifs”.

In the “real world”, where inhomogeneous samples contain multiple components having overlapping absorbance bands, the analytes are subject to interactions with themselves, each other, and the matrix (or solvent) as well as the other components, are affected by extraneous physical phenomena, such as particle size variation, and extraneous conditions, such as temperature changes, and are measured by less than ideal instruments that are prone to noise, drift, non-linearity, and other defects, simply choosing “a” wavelength at which to perform the analysis is not an option: such a wavelength will not exist, probably not even in principle. Add to that brew the fact that very often the “analyte” of interest is not a well-defined chemical species but rather a physical property or operational parameter of some sort (examples of which were described above, where the chemistry and/or spectroscopy is ill defined or unknown), then the question of characterizing the situation by “a” wavelength becomes ludicrous. Consider further the fact that spectroscopic measurements are often taken via reflectance rather than transmittance, so that the measurements are affected by the physical nature of the sample; thus, the choice of a wavelength becomes even more difficult (what is the absorbance band for “particle size effect”, for example?).

There are generically two ways in which all these difficulties can be addressed. The first is to apply known physical and chemical theory to characterize each individual phenomenon that affects the measurement and use that theory to make appropriate corrections. Historically, this is how science has progressed. In principle, this would result in an “absolute” measurement that would be independent of particular conditions existing in each laboratory and would consequently be highly advantageous. There are two difficulties with this approach: first, not all of these obstacles to accurate analysis have rigorous ab initio theories available to adequately describe them and, second, each and every routine analytical application of spectroscopy would then become a major research project (with the attendant time, money, and resource
requirements), preventing spectroscopic analysis from becoming a routine tool, the state of affairs that we currently enjoy.

Therefore, in practice, the second way of addressing the difficulties is used: the situation is treated completely empirically, and following the dictum that “math is cheaper than physics”, the relationship between the composition of a suitable set of samples and their optical properties is derived from the spectroscopic measurement of the samples and computation of the relationships using the sophisticated mathematical procedures mentioned above. Figure 1 presents a block diagram of how this is done.

These procedures have been developed to find empirical ways of accommodating variations in the data that are not describable by fundamental a priori knowledge, through the ability to use information at multiple wavelengths to compute corrections for the physical effects that would otherwise cause errors. Random errors are accommodated by using a large number of readings. This is accomplished by using data measured at multiple wavelengths from many samples, to allow the errors to “average out” so that the net result is close to the “truth”. The procedures used are collectively described by the term “chemometrics” (literally, the measurement of chemistry).

1.2 Generic Procedures

Some considerations are common to all methods of spectroscopic calibration, regardless of the particular mathematical algorithm used. Use of standard good laboratory practice (GLP), such as proper sampling techniques, ensures that the sample measured is representative of the material whose composition is to be determined. Equally important for calibration purposes, it assures that the material measured optically by the instrument is substantially the same as that measured by the reference laboratory.

Good chemical laboratory practice prevents the sample from changing between the time it is taken and the time it is measured. In general, the application of common sense and standard chemical procedures will prevent many sources of error from affecting the measurement process.

In addition, there are some procedures that are unique to the application of the chemometric techniques that are used here. These procedures devolve from the nature of the calibration process, the need to “relate spectroscopically measured quantities to the chemical composition of samples”, as defined above. Thus, to accomplish this, we need to do two things:

1. take the spectroscopic measurements; and
2. determine the chemical composition of the samples, so that we can find the relationships between them. Both of these need to be done properly.

Thus, the concept of “training” the spectroscopic system (usually considered to be the instrument), which comprises the procedures used to find the necessary relationships, arose. To accomplish this, it is necessary to accumulate an appropriate set of samples, measure them using the spectrometer to be calibrated, and have the composition of those same samples measured by some other, independent method (often wet chemical analysis), in order to create the data that the algorithms will be applied to.

1.2.1 Sample Collection

As hinted at above, a single sample is useless for calibration purposes. The methodology of calibration requires that a set of samples be used. Furthermore, although samples are often collected at random out of necessity, not all sets of samples are equally suitable for calibration. Here we discuss criteria for collecting sample sets with optimum characteristics. Although it is usually not possible to achieve and optimize all these desirable characteristics simultaneously, attention to them, and attempts to come as close as reasonably possible, will result in ultimately achieving calibration results that are as accurate and robust as possible.

So, what are the desirable characteristics of a set of samples to be used for calibration? The first critical characteristic is that the samples used for creating the calibration model must be essentially the same as those to be analyzed in the future, using that model. This usually means that actual, real, samples of the type to be analyzed must be collected. Synthetic laboratory samples have been used to calibrate instruments but this is rare as such samples are usually not sufficiently representative of the variations of actual samples from a real chemical process for a calibration model based on them to give accurate results when the actual samples that the calibration is
intended for are measured. This is particularly true when the samples are a natural product, or an intermediate or final product of a chemical process stream.

A second key characteristic is that the samples must cover the range of values of the constituents contained in the samples. It is found that extrapolation beyond the range of constituent concentrations contained in these training samples generally results in very poor accuracy in the extended parts of the range. Furthermore, to include the range of values of the constituents for which calibrations are to be generated is not sufficient. It is also necessary that the calibration sample set includes the range of variation of those constituents that are not measured, but which may exist in the samples and vary from sample to sample. While this is a tall order, the reason for it is clear: it is necessary for the variations of effects of those other, interfering, materials to be present in the sample set so that the necessary corrections can be calculated and included in the calibration model.

It is also most desirable that the various constituents vary independently of each other. In other words, if a set of samples contains two constituents, A and B, say, then constituent B should vary throughout its concentration range in those samples containing low values of constituent A, intermediate values of constituent A, and high values of constituent A. Similarly, constituent A should vary over its range for all values of constituent B.

In those few cases where it is possible to use synthetic laboratory samples, they do have an advantage since they can be made up according to prescribed formulas that can assure the independence of the constituents. However, more commonly, when this method cannot be used, it is necessary to collect "sufficiently many" samples to maximize the chance that the range and independence conditions are met. "Sufficiently many" is obviously not a very concrete description, but the actual number will depend on how much variation can be introduced into the samples while they are being collected.

Some rules of thumb have been devised to help with this. One such rule is that the minimum number of samples should be 10 times the number of constituents, plus 10 more ("for the pot"). Another rule is that, since these calibrations are often used for analysis of samples from some sort of a process, the samples for calibration should be taken during start-up, shutdown, or any other time the process is in a condition other than "normal operation".

Another good piece of advice is to collect samples over long time periods. Often a more or less temporary calibration is created at the time an instrument is first installed, and then more calibration samples collected even while the instrument, with this temporary calibration, is used for routine analysis. In this case, the instrument can even help select which samples to collect: those would be the ones for which the readings are found to be inaccurate.

### 1.2.2 Reference Value Considerations

Few aspects of the calibration process have caused more confusion than the question of obtaining reference, or training, values for the constituents in the sample set. Part of this is attributable to the historical experience of new users of the instruments that need this type of calibration: they are used to depending on their current laboratory procedure for their analytical answers. Normally, this is the same procedure that will serve to provide the values for the composition of the training samples. Since this was always the only value available, it has always been regarded as being "correct". Most chemists know intellectually that every measurement has some error associated with it, but this does not easily translate into an intuitive appreciation for the effects of those errors on an instrument calibration.

With experience, and hopefully from the advice of experienced workers, there comes the realization that the errors need to be quantified, and that there are relatively standard procedures for doing this. If no other rationale can be found, anyone calibrating an instrument should know and appreciate the fact that the instrument cannot be expected to agree with the reference laboratory results any better than those results agree with themselves.

Hence, good practice in this regard indicates that every sample that is to be included in the calibration set (or in the validation set: see below) should have at least two aliquots taken and sent to the laboratory for independent analysis. The samples should be "blinded" so that whoever is doing these reference analyses should not know which of the samples being analyzed represent the aliquot pairs. It is preferable, in fact, that, if the procedure is not too time or resource consuming, the different aliquots be sent on different days, or at least be timed so that they will be analyzed on different shifts; the idea here is to try to "capture" as much as possible of the true laboratory variability in the readings, so as to obtain as good an idea as possible of the true value of the reference laboratory error.

These paired readings can be used for two purposes. The first is to assess the error of the reference laboratory, so that a comparison can later be made with the instrument’s agreement to the reference laboratory values. Normally, a good calibration model will provide results that agree with the reference laboratory results about as well as the reference laboratory results agree with each other. If the agreement between the instrument readings using a given model and the reference laboratory results is too good, then that is evidence that the model has been “overfit” to the calibration data, a calibration problem that will be discussed further below.
The second use of the paired values is to average them together, and use the average of each pair of readings as the reference value for that sample. The process of averaging reduces the error of the analysis, so that the calibration training values are more accurate than single readings.

1.2.3 Data Pretreatments

Spectral data are often converted, prior to applying the main calibration algorithm, to a form different from the absorbance values they are collected in, for the purpose of calibration. Indeed, it could be argued that they are always converted, since spectral data are invariably collected as measured energy, and the absorbance itself is a calculated value. However, since absorbance is invariably the format stored, used for calibration based on Beer’s law and often used for presentation of the spectra, it is considered the “standard” format for calibration work, particularly in the near-infrared (NIR) spectral region, and in others when quantitative analysis is the consideration.

Thus, data transformations almost invariably use the absorbance spectrum as their starting point. The intent of most of the transformations is to remove or reduce variations of the spectra that might cause errors in the calculated results, although some transformations are intended to improve the linearity of the relationship between constituent concentrations and the spectral measurements. There are a number of ways in which the various transformations can be classified; one convenient way is to consider whether they work on individual wavelengths or use the readings from two or more wavelengths to compute the final value corresponding to a given wavelength. Table 1 lists the most common transformations encountered.

Of the pretreatments listed in Table 1, all except the Kubelka–Munk transform are for the purpose of removing extraneous variations superimposed on the spectrum, although the various transformations are designed to remove different types of variations.

Smoothing is the averaging together of several readings in the neighborhood of a nominal wavelength, and is intended to reduce instrumental (or high-frequency) noise. A simple averaging together of the readings at some number of wavelengths on either side of the nominal wavelength with the reading at the nominal wavelength is most effective at reducing this noise, but has the disadvantage of increasing the apparent width of the absorbance bands in the spectrum. A compromise sometimes used is to perform a weighted averaging, whereby those wavelengths closest to the nominal wavelength contribute more to the final value than do those farther away. The classic paper by Savitsky and Golay\(^4\) is often used as the basis for selecting the weighting factors for this transformation (as well as some of the other data transformations used). An alternate method that has been recommended for smoothing spectra is Fourier smoothing (see, for example, Chapter 8 in Burns and Ciurczak\(^5\)), but this method is not widely used.

The remaining methods listed in Table 1 are intended to remove low-frequency noise from the spectra. “Low-frequency” in this case means that it affects all wavelengths uniformly, or at least consistently. Although in rare cases pathlength changes in a transmittance measurement would give rise to this type of variation, it is most commonly seen when measuring reflectance spectra from powdered solids. It is a characteristic of powdered solids that the reflectance depends on the details of the size, shape, and orientation of the surface layer of particles, and hence the same sample will give a different spectrum each time it is reinserted into the instrument and remeasured. The variations are systematic across the spectrum, and therefore mathematical manipulations can correct these variations (or at least bring all readings to a common basis). Some of these characteristics are equivalent to a baseline shift, some are equivalent to a sensitivity change, and others are not describable by such simple means. However, most of the variations can be interpreted as one of those two mechanisms, therefore the listed data treatments address those types of variation.

Normalization is performed on a spectrum-by-spectrum basis. The mean absorbance of each spectrum is computed and subtracted from the absorbance at each wavelength. This corrects the baseline of each in such a way that the average absorbance of each spectrum is zero. The standard deviation of each spectrum’s absorbances is computed and the mean-corrected absorbances divided by that value; this adjusts the scales for the spectra, to minimize sensitivity differences.

Multiplicative scatter correction is similar, except that, instead of bringing each spectrum to an arbitrary baseline and sensitivity, the mean spectrum is computed, wavelength by wavelength, from all the spectra in the calibration set, and then each individual spectrum’s mean and standard deviation adjusted to match that of this mean spectrum.

Table 1

Various orders of the derivatives of spectra (with respect to wavelength) are used to correct baseline variations. The first derivative will correct a constant offset, similar to the subtraction of the mean absorbance from each spectrum. Higher-order derivatives extend this capability by correcting higher-order baseline shifts: a linear shift can be corrected by a second derivative, a quadratic (parabolic) shift by the third derivative, etc. Computing derivatives has no effect on differences due to sensitivity changes. Computing derivatives, however, has a disadvantage in that it emphasizes the high-frequency noise. It is usually necessary, therefore, to apply a smoothing transformation to the spectra as well.

Ratios are used to compensate for sensitivity (and pathlength) changes. Ratios of absorbance to that at a chosen wavelength, to a derivative, and other combinations have been tried, with varying success. A difficulty arises when the true “zero” for the spectra cannot be determined; this may be the cause of the lack of success in some cases.

Finally, the Kubelka–Munk correction has been used to obtain a more linear relationship between the spectral readings and the concentration composition of samples measured by reflectance. The reflectance \( R \) at each wavelength is back-calculated from the absorbance, and then the Kubelka–Munk function is computed from Equation (2):

\[
f(R) = \frac{(1 - R)^2}{2R} \tag{2}
\]

Since the theory upon which this is based requires that \( R \) be known in absolute terms, this approach also encounters difficulties when the true zero and true unity reflectance cannot be determined.

### 1.2.4 Calibration

The process of applying one or more of the various algorithms used to relate the spectroscopic data to the compositions of the training samples constitutes the “calibration” process. The algorithms used will be discussed below. What is important to remember is that, regardless of the algorithm, certain considerations should be kept in mind. The mathematics behind all the algorithms are based on certain assumptions being met. Depending on the computer programs used to implement the calibration procedure, the software may or may not automatically test whether the data at hand conform to these assumptions. Good practice indicates that such tests should be made in any case. Information about the underlying assumptions and ways to test the data can be found in Draper and Smith.(6)

In addition to not meeting the fundamental assumptions, data can be defective in other ways, e.g. contain outliers or be nonlinear. Draper and Smith discuss ways to examine data for various defects; a discussion more directed to the effects found in spectroscopic data is given by Mark.(5)

An additional consideration involves the question of how many factors’ worth of data to use in a given calibration model (or, alternatively, how many wavelengths, where that is the appropriate consideration) and which ones. Including too few factors results in a model that does not account for all the interferences in the samples, and thus is inaccurate.

Including too many factors (or wavelengths) results in a model that is “overfit”, i.e. it tends to model some of the random noise present in the data rather than the systematic variations due to real physical phenomena, and therefore it is not robust. That is, it will not stand up to variations in the samples, their preparation, the instrument, or the environment, and thus the long-term accuracy is compromised.

Therefore, finding the optimum number of factors, and the correct ones, to include in the model is crucial to obtaining best performance. Some of the statistics produced by calibration software help in this search. Some experts recommend creating several calibration models, monitoring their performance over time, and weeding out those that are deficient in accuracy or robustness.

Another recommended practice, mentioned above, is to improve the robustness by continuing to collect samples over time and including them in the calibration calculations. This procedure will eventually include all the variations normally seen in the calibration samples.

### 1.2.5 Testing the Calibration Model

Whenever a calibration model is created, it is necessary to ascertain whether that model can accurately analyze the constituents in the samples it is intended for. To this end, a number of statistics have been devised, to test different aspects of the performance of the calibration model. An exhaustive list would be impossible to present, since all statisticians have their own favorite set of statistics to use for this purpose. However, some common ones are:

1. **Standard error of estimate (SEE, sometimes called standard error of calibration SEC):** the standard deviation of the errors found for the samples in the calibration set. This value should be compared with the accuracy of the reference laboratory in order to determine whether the calibration model can be improved. If the SEE is smaller than the error of the reference laboratory, the model is probably overfit.

2. **Multiple correlation coefficient \( R \):** a dimensionless number. The minimum value of \( R \) is zero; this happens if there is no agreement between the reference...
laboratory values and the analytical values found using the instrument with the calibration model under consideration. The maximum value of $R$ is unity; this is obtained when the instrumental measurements agree exactly with the reference laboratory measurements, with absolutely no error. Usually, neither of these extreme values is seen: intermediate values are inevitably found. An average “good” calibration will achieve a value of $R$ between 0.90 and 0.95, while a superior calibration may attain a value of 0.98–0.99, or even higher.

3. Standard error of prediction (SEP; sometimes the abbreviation SECV (standard error of cross-validation) is found in the literature (incorrectly) used in place of SEP): the standard deviation of the errors found for samples not in the calibration set (see section 1.2.6).

1.2.6 Validation

“Validation” is the name of the process used to assess the performance of a calibration model. Although there is some disagreement over the exact meaning of the term, the majority opinion at this time is that it consists of ways to estimate the accuracy and robustness of any given calibration model at the time it is created.

There is widespread, even universal, agreement, however, that the best way to determine these qualities is to have a set of samples, similar to but separate from those used to create the calibration model, that also have known constituent compositions (normally from measurements made using the same reference laboratory procedure applied to the calibration samples themselves). When any calibration model is created, it is used to analyze these validation samples, and the result of that analysis is compared with the reference laboratory values. If the agreement between these two sets of analyses (as measured by the SEP) is approximately the same as the agreement for the calibration samples (as measured by the SEE), then, subject to the qualification that the results of any other statistical tests carried out are satisfactory, the model is probably a valid one, and will continue to perform at the accuracy that the SEE and SEP indicate.

1.2.7 Prediction (Analysis)

Whether the intended purpose of the instrument (along with the corresponding calibration model) is raw material inspection, quality control (QC) of product, or any other purpose, this purpose is realized in the actual ongoing routine analysis of the samples for which the calibration model was created. Good practice indicates that the performance of the calibration model used should be monitored on an ongoing basis, by comparing the results from the instrument with those from the reference laboratory at periodic intervals. A continuing QC process of this sort will guard against inaccurate analyses due to instrument malfunctions, as well as other error sources that can occur, such as carelessness in sample handling and preparation.

Indeed, a minority opinion extends the concept of “validation” to include this ongoing QC process. There is also a proposal that several calibration models be created and subjected to this extended validation process; then the best model will be chosen after evidence is available as to which model is in fact most accurate and robust.

2 INDIVIDUAL-WAVELENGTH METHODS (ALSO CALLED MULTIPLE LINEAR REGRESSION, P-MATRIX, INVERSE LEAST SQUARES, AND ORDINARY LEAST SQUARES) AND WAVELENGTH SEARCH TECHNIQUES

We now come to the point of dealing with the various mathematical methods that have been developed for actually relating the spectroscopic measurements to the samples’ compositions. There are a number of ways in which these can be organized, each of them justifiable. I do not think that one way is so superior that it sticks out as the “best”, but since there must be some sort of organization imposed on the many methods available, the one used is simply one that is convenient, and perhaps somewhat idiosyncratic in that it is attuned to the way I think about them.

Figure 2 illustrates the situation. Here there are three spatial dimensions; these dimensions can represent three
wavelengths (or three abstract “factors” as will be discussed presently). Each combination of the three wavelengths will have a calibration model associated with it, and that model will have some performance characteristics, which are characterized by the values of the auxiliary statistics for that model.

Certain combinations of the factors will have better performance than others. The density of points in Figure 2 represents the “quality” of the calibration, as evidenced by the values of the auxiliary statistics, which are thus seen to be localized in the vicinity of those optimum combinations of wavelengths.

The general problem is to find those regions of optimum performance representing the wavelength combinations at which the spectral data give the best analytical behavior. For models based on more than three wavelengths, the situation is the same. The main difference is that it is not possible to draw a picture to show four, five, or more dimensions. The problem of finding the best wavelength set also becomes more difficult, but there is no change in its basic nature.

The existence of more than one region of apparent optimum performance complicates the situation, because some algorithms will find one of these “local maxima” and stop searching before finding the global optimum. On the other hand, often the local maximum will behave almost as well as the global maximum, so that in practical terms it makes no difference. The main problem then is to compare models, developed at different times, resulting from these different wavelength choices. A similar situation exists for models based on full-spectrum algorithms. One solution to this dilemma will be discussed shortly.

Historically, individual-wavelength methods were the first to be developed and put into widespread use. While Malinowski may have developed K-matrix (see below) methods contemporaneously with, or possibly even a bit earlier than, Norris’ work, this approach was pretty much restricted to academic research laboratories. It was the application of multiple-regression analysis (also now called P-matrix) methods by Karl Norris to NIR spectroscopy that brought calibration out of the academic laboratory and into regular commercial use. The P-matrix methods depend on the careful selection of a relatively small number of wavelengths from the spectrum, and the use of the spectroscopic data at those wavelengths to perform the analysis. Hence, a good deal of effort has been expended in investigating ways to find the “best” wavelengths.

To a large extent, the use of P-matrix methodology has been superseded by full-spectrum methods, although it is lately enjoying a slight resurgence, partially because of the new methods of wavelength selection that are being developed.

Therefore, it is worth spending some time discussing this approach because of its historical importance (to help understand the current and future status of this topic), because it is eminently suited to use with lower-cost instrumentation, and because new research reveals situations in which this approach can provide superior results, which may further promote its future applications.

In general, all of the wavelength-search methods are based on selecting some test set of wavelengths and performing a trial set of P-matrix calibration calculations, including the auxiliary statistics, using the data found at those wavelengths. These calculations are then repeated using a different set of test wavelengths, and the statistics from the two trial calibrations are compared. The set with the better statistics is retained. This process is then repeated for however many trial sets of wavelengths are predetermined by the wavelength-search process being used; when this phase is complete, the best wavelength set found, along with the results from the corresponding calibration, is reported.

This procedure presupposes the existence of a larger set of data from which the trial sets of wavelengths are drawn. Normally, this larger set is composed of optical readings at a continuum of closely spaced wavelengths, i.e. a spectrum. The question that immediately comes to mind is: “Why not simply use all the data available?” The answer is multifold, but in general it has to do with the mathematical properties of such large sets of data. The mathematics of some types of algorithms, for example of the multiple-regression (P-matrix) approach require that there be more samples’ worth of data than there are variables, otherwise divide-by-zero errors will necessarily occur during the intermediate calculations (e.g. during the matrix inversion). In other cases, the nature of the data itself is such as to cause difficulties of that sort; even if the problem is not so extreme as to cause divide-by-zero error, a lesser degree of that characteristic of the data can, and will, cause the final model calculated to be useless (in the sense that it would be even more inaccurate than simply guessing), and any tests involving it will become meaningless.

2.1 Classical Methods

The wavelength-selection methods can further be divided into “classical” and “modern”. The classical methods are loosely defined as those developed before the full-spectrum methods gained ascendancy, and the modern ones are those developed since then, and are helping the P-matrix approach make its comeback. Again, this division is purely idiosyncratic on my part, but it helps keep the various methods in historical perspective. There are also, as we will see, some significant differences in the nature of the search process between the two groups.
2.1.1 Searches at Constant Numbers of Wavelengths

The hierarchy of wavelength-search methods can further be broken down into those that maintain a constant number of wavelengths and those that change the number of wavelengths used in the trial models. Although in actuality these are often combined, it is pedagogically useful to describe them separately.

The search procedures that maintain the number of wavelengths constant are, relatively speaking, easier to compare and evaluate. This is because all the statistical descriptors will improve or degrade simultaneously as different trial models are calculated and compared. Therefore, using any of these descriptors will provide an unambiguous choice of which model to retain for future comparisons during the wavelength-search, a property that is not necessarily maintained when comparing models with different numbers of wavelengths.

2.1.1.1 All Possible Combinations One solution to the problem of finding the best wavelength combination is to try all possible combinations of wavelengths. This is really the only method guaranteed to find the global optimum. It will do this even if the data are discontinuous, i.e. if only separated segments of the spectrum are available, or even if, as in interference filter-based instruments, spectral data at only sporadic and arbitrary wavelengths exist.

There are actually two definitions of “all possible combinations”, and users should make sure that they know which definition applies to any software package in use. By one definition, trial models for the wavelengths taken at a time are calculated; all those models contain \( m \) wavelengths. By the other definition, the software calculates all \( 2^n \) trial models for the wavelengths taken 1, 2, 3, …., \( n \) at a time. The second definition is more comprehensive but introduces the difficulty of comparing models containing different numbers of wavelengths.

By either definition, the main limitation of this approach is the amount of calculation required. Since the number of models that need to be tested increases factorially or exponentially as the number of wavelengths available, or the number of wavelengths in the model increases, the amount of computation can quickly overwhelm any physical computer, and require computation time many times that of the lifetime of the universe. Software exists to mitigate these limitations, in order to make the use of the all-possible-combinations approach feasible, but care must still be taken to avoid bogging down the computer this way.

2.1.1.2 Seek and Replace The general idea behind this method of seeking the next wavelength set is to sweep one trial wavelength at a time through the spectrum, and find the wavelength in the spectrum that gives the best model in conjunction with the other wavelengths, while those others are held fixed. Figure 3 illustrates this procedure, for a search for a three-wavelength model, compared with the spectrum, which is indicated by the horizontal line. Figure 3 indicates the starting configuration, which in this case has the three wavelengths all starting from one end of the spectrum. This is not necessarily the case in actual search software, where the initial configuration may be determined by applying extraneous chemical or spectroscopic knowledge, or even by choosing the wavelengths randomly. However, showing all the wavelengths as starting from one end of the spectrum is convenient pedagogically. At step 1, the “first” wavelength is swept through the spectrum and the best model noted, so that after step 1 we see that one of the wavelengths is in its optimum position. Then the “second” wavelength is swept through the spectrum so that after step 2 another one has been optimized, and after step 3 the third. There is a temptation to stop at this point and declare the search complete.

In practice, however, it is found that the optimum wavelength for any one of the trial wavelengths depends on the actual wavelengths of the others. Therefore, it is necessary to sweep the “first” wavelength through the spectrum again, and continue through the trial wavelengths, sometimes several times, before the best set is found. This is usually considered to be achieved when the set of wavelengths becomes stable, that is, sweeping any of the individual trial wavelengths through the spectrum does not find any different wavelength which provides an improved model compared with the current
actual wavelength, so that no new wavelength is chosen. In our example, shown in Figure 3, this occurs at step 5.

### 2.1.2 Step-up Searches

The main limitation of any search methods that restrict the number of wavelengths to a constant number is, in fact, just that: that the number may be too few or too many for an optimum model. As described in section 1.2.4, a model with too few wavelengths will not allow that model to correct for all the interferences present in the samples, and one with too many will overfit the data, with a consequent lack of robustness. One common way in which these difficulties are addressed is by using “step-up” (adding wavelengths) and “step-down” (deleting wavelengths) procedures. The step-up procedure is perhaps the easiest to describe, since in one implementation it builds on the seek-and-replace algorithm described in section 2.1.1.2.

Basically, from the best model found using \( n \) wavelengths (say, the three found in Figure 3), a new model is sought using \( n + 1 \) wavelengths, in which the ones already found determine the starting configuration for the search for \( n + 1 \)st. This situation is shown in Figure 4, in which a fourth trial wavelength is added to the three found in the previous search. Normally, the new wavelength added would be the first one to try to improve by sweeping it through the spectrum, as shown, and continuing from that point as before.

In general, given a set of \( n \) wavelengths, it is possible to step up from that set as the starting point for finding \( n + 1 \). This, however, leaves open the question of how to start the search. In principle, there is no reason why one should not simply start from zero wavelengths and search for the best single one. However, in practice, it is often found that this does not lead to such good models as when a search for the best two or even three wavelengths, using a different search method (e.g. all-possible-combinations) is used to start the search going.

### 2.1.3 Step-down Searches

A step-down search, of course, is just the opposite of a step-up search. That is, having found a model using \( n \) wavelengths, one of these wavelengths is deleted, so that a model containing \( n - 1 \) wavelengths is calculated.

However, when starting a new calibration development effort, no wavelengths have yet been chosen; in order to “step down” it is desirable to then include all available wavelengths in the first trial model. In order to avoid the problems (described above) encountered when applying multiple linear regression (MLR) calculations to full spectra data, this procedure is sometimes used when the spectral array does not contain data from many wavelengths, for example when the data are from an instrument using a limited number of interference filters. One reason why this approach is limited to that type of data is that it is necessary (as it is always necessary when using an MLR-type of calibration methodology) to have data from many more samples than there are wavelengths in the calibration model. Since the maximum number of wavelengths can be no more than the number of filters in the instrument, this helps ensure that the condition is met, even though data from all the available wavelengths are included in the model. Including all wavelengths also insures that no potentially useful wavelength is excluded from the trial wavelengths.

This approach to calibration also has the advantage of being the least computation intensive of the methods so far discussed. The reason for this is that, when all the available wavelengths are already included in the calibration model, it is a relatively easy task to determine which are contributing the least to the model’s performance, and to delete that one. It is therefore rare that it is necessary to sweep the various trial wavelengths through the spectrum multiple times, as was necessary in the step-up approach. In fact, if the software provides the appropriate statistical outputs along with the calibration model itself, no sweeping of any wavelengths is needed; the wavelength that can be deleted can be determined directly from these auxiliary statistics.

### 2.2 Modern Methods

It is possible to distinguish between the “classical” and the “modern” methods of wavelength-selection in two ways, which give the same classification of the methods but provide some different insights into the historical and technical developments of the techniques. One method of drawing the distinction is the one described in section 2.1: the temporal relationship between the methods and whether they were developed before or after the full-spectrum calibration methods became popular.

The other way of distinguishing them is as follows: if the various classical wavelength-selection methods described in section 2.1 are examined, it can be noted that, although the modeling calculations themselves are multivariate,
the wavelength-search patterns used to find the proper, or best, wavelengths are, by analogy, univariate. That is, only one wavelength at a time is changed and its effect on the calibration model examined. By contrast, the modern search algorithms are multivariate in the search patterns as well as in the model generation calculations. That is, the search algorithms vary the locations of two or more wavelengths within the spectrum simultaneously, and compare the various models generated by those more complicated sets of wavelengths.

The advantage of these algorithms is that they are computationally much less intensive than, say, the all-possible-combinations search, while having a greater likelihood of finding the best wavelength set at which to create the model than the “classical” search methods.

2.2.1 Simplex Optimization

The generic concepts of simplex optimization are nicely described by Walters et al. The advantage of simplex optimization as a wavelength-search technique is efficiency: in general, a simplex will find an optimum set of wavelengths more surely and with much less computation than most other wavelength-search methods.

A simplex is a generalization of a triangle to higher-dimensional spaces. As we saw in Figure 2, for example, in the types of multidimensional spaces that are of interest to us, the axes of the coordinate system of that space represent wavelengths, and in Figure 2 the values of the quantity that varies in that space are represented by the density of the points. In Figure 2, the quantity that varies throughout that “space” of wavelengths is the “goodness” of calibration models, and so the density there is proportional to the “goodness”.

To represent this situation in a small number of dimensions, a diagram can be created such as that in Figure 5(a), in which two axes represent wavelengths and the third axis represents the “goodness” quantity. In this case, the way in which “goodness” varies can be represented by a surface. This situation is shown in Figure 5(a). The simplex, in this case, is an actual triangle: the small triangle shown that represents the search plan. Each corner of the triangle represents two wavelengths and the “goodness” parameter of a model at those wavelengths. Being a triangle, the simplex lies in a plane, and this plane is embedded in the surface representing the responses. The triangle (simplex) moves around the surface, seeking the location of the optimum response. It moves by replacing the existing triangle with one that has two corners the same but a third corner that has moved to a location where the response has improved over the response at its original location on the surface. Successive moves of this sort quickly bring the simplex to the optimum position at the “top of the mountain”, where the response is optimum. Each move thus causes both of the wavelengths corresponding to that corner of the simplex to change simultaneously.

Figure 5(b) shows the similar situation, extended to the case of three wavelengths (plus one response axis, giving a four-dimensional situation); indeed, this figure is almost a duplicate of Figure 2. In this four-dimensional case the simplex is, as shown, a tetrahedron: a three-dimensional object. The tetrahedron moves in a manner similar to the triangle; here, however, three wavelengths change whenever one corner of the simplex moves.

In general, the dimensionality of the space is one more than the number of wavelengths, while the dimensionality of the simplex is one less than the dimensionality of the space. Diagrams for higher dimensions (i.e. more wavelengths) cannot be drawn, but expressing them mathematically, or in a computer program, is relatively straightforward.
2.2.2 Genetic Algorithms

This topic is discussed for the sake of completeness, since at this time (at least as far as we know), this method of wavelength-selection is used only for research purposes and no commercial implementations are available for routine analytical use. More extensive discussions than we can provide here are available in the literature (see Jouan-Rimbaud et al.\(^8\)).

As will be seen, while the genetic algorithm approach to wavelength-selection is similar to the simplex optimization approach in that it provides for changing several wavelengths at once, it differs in one key respect: it provides for different numbers of wavelengths to be included in the various models, whereas the simplex can only generate models containing a predefined number of wavelengths.

Genetic algorithms are based on, and named after, analogous operations in biological evolution. The spectrum of a set of samples is considered analogous to a chromosome, and wavelengths selected from those spectra are thus analogous to genes. Just as biological systems (organisms) evolve by selection of the most successful genes from all the combinations that are created at random, so too is a calibration model allowed to “evolve” by selecting the most accurate and robust model(s) from randomly created sets of trial combinations, following rules that cause the process to behave in a manner analogous to phenomena found in nature.

Figure 6 shows the effects involved. A number of “chromosomes” (spectrum segments) and “chromosome fragments” are available for recombination. Some of these “chromosomes” are subjected to random effect analogous to “mitosis” and “recombination” of the genes (wavelengths). In Figure 6, for example, the “chromosome” containing “genes” w10, w11 and w12 is undergoing “mitosis” – splitting into fragments. Figure 5 also shows two fragments joining: the “chromosome” containing “genes” w4 and w5 is joined to the one containing “genes” w13 and w14 to form a new “organism” containing four “genes” in its “chromosome”. Each time a new “chromosome” is formed, by either splitting or recombination, the “fitness” of the “organism” to survive is determined by computing the calibration model corresponding to those “genes” (wavelengths) and “only the fit survive” to “breed” a new “generation” of calibration models, i.e. only those calibration models meeting a minimum criterion for performance are retained to use for trying new combinations of the available wavelengths. In this manner, better and better combinations of wavelengths are found as succeeding “generations” of wavelengths are developed and tested.

Normally, a “mutation” mechanism is also introduced into the system. The “mutation” is the random introduction into a “chromosome” of a new “gene” (wavelength). Through this mechanism, a wavelength that has not been used before can be tested for its effect on the “evolution” of the calibration model, thereby removing what would otherwise be a restriction on the possible wavelengths to only those wavelengths initially introduced. With “mutations” introduced, any wavelength present in the spectrum can be given a chance to contribute to the calibration model.

3 FULL-SPECTRUM METHODS

These were originally developed to overcome the difficulties encountered in the individual-wavelength methods, of selecting the proper wavelengths and the proper number of wavelengths to include in a calibration model. Historically, they were also developed simultaneously with the development of full-spectrum instruments (NIR interference filter-based instruments were commercially available before other types, particularly diffraction-grating-based instruments), and it seemed sensible to use the full-spectrum capability of the instrument by including the full spectrum’s worth of data in the calibration model.

It is not mathematically possible to include the several hundred wavelengths’ worth of data typically produced by a diffraction-grating-based instrument (or any of the other full-spectrum instruments) in an MLR calibration calculation. The data must somehow be modified in order to reduce or remove intercorrelations. Indeed, this is one of the major purposes of selecting wavelengths when performing MLR calibrations. If we prespecify, however, that wavelength-selection is not an allowed option, then other methods must be used to perform that task.
3.1 Generic Considerations

While these methods are classified as “full-spectrum” methods, that is merely a convenient label, used to distinguish this class of algorithms from the “individual-wavelength” algorithms: it is not necessary in fact to have a full spectrum’s worth of data in order to apply these algorithms. Disconnected sections of spectra, individual wavelengths, and even mixtures of these are all satisfactory as input data for these approaches. The point, however, is that none of the data is left out of the calculations; whatever is available is included.

We have seen that we cannot simply carry out regression-type calculations using data with so many wavelengths that intercorrelation is severe. Even more importantly, it is not possible to perform regression-type calculations when there are more wavelengths (or variables) than samples, as there often are when the instrument produces several hundred or even several thousand wavelengths’ worth of data from each sample that is measured.

The full-spectrum methods work (i.e. allow all the wavelengths to be used) by reducing the intercorrelations among the data used in the final regression step by means other than deleting the wavelengths.

Normally, this is accomplished by transforming the spectral data, by some means, into other variables. These “other variables” (sometimes called “latent variables”) are defined and derived in such a way that they can be used to reconstruct, or recreate, the data spectra. There are two parts to this: the spectra are replaced by the sum of other “spectra” that have desirable properties; the main property of these other spectra is that each of the original data spectra can be expressed as a weighted sum of the replacements. The replacement spectra are called “factors”.

In addition even though each one of the factors is formed from, and contains information from, the entire spectrum, they often have the desirable property that they are uncorrelated with each other; this is desirable because it means that the contribution of any one factor to the original data spectrum is unaffected by the presence or absence of any other factor. The mathematics behind the transformations that provide these properties is very complicated and sophisticated, and far beyond the level of this article. However, we can get a conceptual idea of what and how this is accomplished by inspecting Figure 7. The concept of a “spectrum” has been simplified in Figure 7 in order to concentrate on the salient points. The “data spectrum” of Figure 7 is marked at the top of the figure. The spectrum, and the factors, each have their own zero line for reference. The zero lines are the heavy horizontal lines associated with the four functions of interest (the spectrum + three factors). The “factors” shown in Figure 7 have the following two properties:

1. A suitably weighted sum of these factors can be added up to recreate the spectrum.
2. Each factor has both a positive and negative section to correspond with a positive section and a negative section of the other two factors, i.e. one part of the positive section of factor 1 corresponds to a positive section of factor 2 and the other to a negative section of factor 2.

The important point about this idealized conceptual spectrum and the factors is that they share the properties of real spectra and factors. Property 1 is the crucial one; all decompositions of spectra into factors must provide factors that have this property. Property 2 is the one that causes the factors to be uncorrelated, as described above. This desirable property is called “orthogonality”.

In principle, there is an infinite number of ways that a set of spectra can be expressed as the sum of other functions (i.e. other spectra), because there is an infinite set of possible mathematical functions that can be used for the reconstruction process. These sets of functions are also called “basis functions”, “basis factors”, and “latent variables”. In practice, there are only a relatively few types of basis functions that are of interest to spectroscopists who wish to use this approach for calibration purposes.

Figure 8 shows how the calibration procedure must be modified, to use the “latent variable” or “factor” approach. We can compare Figure 8 with the calibration procedure shown in Figure 1 to see how the two approaches are related. The factors are represented by a set of values that can be put into a one-to-one correspondence with the values at each wavelength.

Figure 7 Factor orthogonality requires that the sum of the cross-products between any two factors be zero. To accomplish this, equal numbers of positive and negative cross-products must be present, as in the simplified case shown here, where this is achieved by having the negative and positive parts coincide, and in equal ranges.
Those encountered; the question is then how to choose among commonly used, there are at least four that are commonly of these, but even limiting this discussion to those that are wavelength-selection domain.

The existence of different sets of basis functions has no analog in the wavelength's Fourier conversion) is analogous to the multiplicity of cosine waves of different frequencies when performing any given type. The multiplicity of functions that might be used, in addition to the multiplicity of basis factors that are used to decompose the spectra. The different type of calibration algorithms that are in common use are thus distinguished by the nature of the basis factors that are used to decompose the spectra. When reading the chemometric literature, this difference in usage should be kept in mind.

There is another difference between these various procedures, however, that has to do with the nature of the basis functions themselves, that is the method used to create the various basis functions in any given set. Some types of basis functions are based on a priori mathematical considerations. These are not discussed here to any great extent, since the mathematical bases of these can be found elsewhere, in books dealing with calculus or other higher mathematics, with much more complete explanations than could be provided here. The rest of the calibration algorithms rely on basis functions that are created from the data themselves; those will be discussed in more detail, especially their relative advantages and disadvantages.

The last generic issue to be dealt with concerning calibration is the question of, having selected a set of basis functions as the foundation of the calibration algorithm, how to select the actual set of functions that will be included in any given calibration model. In fact, there is potential here to apply any of the selection algorithms that are used to select wavelengths, but this is rarely, if ever, done. There is good reason for this; since many of the basis functions are chosen so as to be mutually orthogonal, the effect of the inclusion or exclusion of any given function on the model is independent of the presence of any of the others, therefore the decision may be based much more confidently on the values of auxiliary calibration statistics, which greatly simplifies the selection procedure.

The calculation of the calibration models in these cases, however, has an important extra step: the calculation of...
Thus, it does not suffice to measure the spectra of the pure materials and use them in an unmodified form. This difficulty can be circumvented by calculating the spectra of the components in the mixture from spectra of mixtures, which can be achieved if enough of the necessary information is available. By measuring the spectra of a suitable set of mixtures of known composition, it is indeed possible to calculate the spectra of the components as they exist in the mixture, which are the needed and desired spectra. Several authors also describe how these calculations are performed (Beebe et al.,(2) p. 218; Kramer,(9) p. 52). The terminology used is indirect CLS.

Another difficulty arises here, though: it is necessary to know the concentrations of all the components in the mixture, whether they are of analytical interest or not. In many cases, not only are there more constituents that are not of interest than that are of interest, but often the reference analyses for those constituents are more difficult, error prone, and resource intensive than for constituents that are actually of interest. This difficulty has prevented this approach from becoming of commercial interest and it has remained more of a curiosity in academic research laboratories.

In a simplified situation, we could imagine the basis functions being computed as the difference between the spectra of pairs of mixtures, each containing one component at a “low” concentration and one at a “high” concentration, with “everything else the same”. Each difference spectrum would clearly represent the spectrum of that constituent, as it exists in the mixture. In the real world, with noise and other nonidealities in the data, the extraction of such approximations to the pure component spectra must be done by regression, in a manner similar to that in which regression was needed to compute the models in the individual-wavelength cases, instead of just solving the simpler case of multiple variables in multiple equations there.

Figure 10 shows a block diagram of the K-matrix approach. Compare Figure 10 with Figure 8, to see how not having the basis functions available a priori complicates the process. To compute the basis functions from the available data is normally the most difficult and computation-intensive portion of these types of calibration modeling algorithms. Note that both the spectra and the set of corresponding concentration values are used twice: once to compute the basis functions and again to compute the final model. This dual use is generally found in all the algorithms that require computing the basis functions from the data. Another distinction of the K-matrix approach is that during prediction, because the basis functions are not orthogonal, the computation of the scores must also be done using a regression approach rather than the simpler cross-product computation used in those cases where the basis functions are orthogonal.

Figure 9 For a factor-based prediction, the scores replace absorbances just as in the calibration.

3.2 K-matrix

The K-matrix approach to calibration was, perhaps, one of the first to be developed, although it never got far beyond the walls of academia. This algorithm is the direct application of the concepts behind Beer’s law, and in modern times is still called “the Beer’s law method”. It is sometimes seen in other guises, for example spectral subtraction, which is essentially the same concept used in reverse.

The idea behind the K-matrix approach is that, assuming linearity of the instrument and non-interaction of the components, the absorbance spectrum of a mixture is composed of the combined absorbances of the components of the mixture, and can thus be recreated from the spectra of those components. In light of earlier discussion in this article, this causes the spectra of the components to be the factors. A mathematical description of this approach is available in a book by Beebe et al.,(2) (p. 188). The nomenclature used by Beebe et al. for this process is “direct (classical) least squares (CLS)”.

Although theoretically sound, this concept has a major limitation: the assumption that the spectra of the components of the mixture are the same as their corresponding spectra in the pure state is often not valid.
Note the key difference between the regression used here to create the factors and the regression used earlier to create a calibration model directly from individual wavelengths, even though both use the spectral data and the constituent concentrations: in the earlier situation the spectral data were regressed against the constituent concentrations, whereas here the roles are reversed, and the constituent concentrations are regressed against the spectra. The details of this are also described by Beebe et al. and Kramer.

Finally, it must be reiterated that the defining characteristic of the basis functions determined by the K-matrix approach is that they are estimates of, or approximations to, the pure-component spectra.

### 3.3 Principal Components

The principal-component approach to calibration is another calibration method based as factors or basis functions which also uses factors that are defined by the set of spectral data from which they are computed. (See also Kramer, pp. 103–106). There are some notable differences between the factors produced by this method and the ones created by the K-matrix algorithm.

First, the factors produced are orthogonal. This is a mathematical property that will not be examined in any depth here. Note, however, that it provides the convenient property, mentioned previously, that the contribution of each factor is independent of the contribution of any of the other factors, in the behavior, i.e. the accuracy and robustness, of the calibration model.

The second difference is that the factors are abstract. Whereas the factors produced by the K-matrix algorithm (particularly the indirect least-squares method) recreate the spectra of the pure components, the basis functions created by the principal-component algorithm do not necessarily have any relationship to any particular physical characteristic of the samples used in their creation. This can happen by coincidence, however, and it is not uncommon to see various signatures of the underlying component spectra in principal-component factors. In Figure 11 the flow of computation involved in the computation of a principal-component calibration model is presented.

The third difference between this algorithm and K-matrix calibration methodology is that, whereas computation of the factors comprising the K-matrix requires both the spectral data and the compositions corresponding to each sample, the computation of the principal-component factors requires only spectral data; the composition does not enter into the factor computation but only into the computation of the final model.

The fourth difference is also the difference between the principal-component algorithm and all other methods of calibration modeling procedures, since it is the key defining characteristic that distinguishes the principal-component algorithm from all other methods of creating basis functions. The key defining characteristic of principal components, which distinguishes them from all other sets of basis functions, is that, when they are used to reconstruct the original data spectra from which they were created, they can do so with less error than any other possible basis function or set of functions. That is, the first principal component can reconstruct the data spectra better than any other single function, of any type. The first two principal components can reconstruct the data spectra better than any two functions can, whether based...
3.4 Partial Least Squares

The partial-least-squares (PLS) algorithm is an attempt to improve on the factors produced by the principal-component calculations and to create basis functions that can better relate to the constituent compositions, rather than simply being the ones that best relate to the spectra. PLS has been widely adopted, and several treatises are available that describe the algorithm in detail.\textsuperscript{(12,13)} (See also Kramer,\textsuperscript{(9)} pp. 139–142).

Figure 12 provides a simplified overview of the workings of the algorithm. Some key differences from the K-matrix algorithm, and some differences from the principal component algorithm are apparent.

A major difference of the PLS approach from the other methods can be seen from an appraisal of Figure 12: information from the constituent concentrations of the samples is included in the computation of the factors. Algorithms exist that do not require iteration and this is illustrated in Figure 12 by the cyclic flow of computations between the model, the factors, the scores, and back again. This is indicative of a key characteristic of the algorithm shown: rather than working solely with a set of factors that model only the principal variations of the spectral data in isolation, it also includes a contribution from the information about the constituents. This inclusion of the constituent information in the factor computation modifies the factors so that they are better able to model these constituents, rather than solely modeling the spectra.

While the PLS method is somewhat similar to the principal-component method in that the PLS factors are partially determined by their ability to reconstruct the spectral data, the inclusion of the constituent concentrations in the loop calculations causes those factors to be “rotated” (this is the statistical nomenclature used to describe this operation) in multivariate space to a direction that causes the factors to become more predictive of these concentrations; this rotation distinguishes the PLS factors from principal-component factors. They also differ from principal-component factors in that PLS factors are not necessarily orthogonal.

The PLS factors differ from K-matrix factors in that, like principal-component factors, they are abstract, as discussed above. Also, the PLS factors are optimized for their task of quantitative analysis. Neither K-matrix factors nor principal-component factors are necessarily optimized for this purpose, since they are defined and computed to meet other criteria.

3.5 Fourier Transform

The Fourier transform approach is, perhaps, the simplest of the algorithms discussed so far. This is because the basis functions used are defined by a priori mathematics: sine and cosine functions. This being the case, the calibration and prediction explanatory diagrams are exactly those presented in Figures 8 and 9, with the arbitrary (factors) designation replaced with the sine and cosine functions, the full set of functions consisting of the sines and cosines of various frequencies. The use of this approach was developed by McClure for use in connection with NIR analysis; an extensive description is available: see Chapter 8 in Burns and Ciurczak.\textsuperscript{(5)}

An interesting use that McClure made of this calibration methodology was data compression. Since the Fourier components can be calculated from a priori mathematical considerations, it is not necessary to maintain a copy of the basis functions along with the model in order to do predictions, as is often required by other full-spectrum methods. In those cases, a copy of the exactly calculated basis functions must be associated with the rest of the model, since each set is unique to the data set from which they were calculated.

Thus, McClure found that a large saving in computer storage space could be achieved, since each spectrum could be represented by only a relatively few of the Fourier coefficients, and the full spectrum reconstructed from just those values, since the basis functions themselves could be calculated on the spot when needed, from their definition.

This calibration methodology never gained widespread acceptance, and has lately fallen into disuse.

3.6 Neural Nets

This is one of the newer calibration methodologies that has been developed, and currently enjoys the status of being used mainly for academic research, although that situation is likely to change, and is the reason it is discussed
Figure 13 Block diagram showing the generic procedure for generating calibration models using a neural net procedure.

The input layer represents the input data, or spectrum, so the number of input nodes would ordinarily equal the number of wavelengths in the spectrum. The output layer represents the results; but the nodes of the output layer also include computation capability, as do the nodes in the hidden layer. The hidden and output layers are where the computations are performed, to create the model that allows calibration results to be formed from the input data. Each node of the output layer can be seen to represent the results of models for a different constituent. The nature of the computation determines the output result, and the computation internal to a node is termed the transfer function of the node.

Each node in one layer is connected, as shown, to all the nodes in the next layer and, conversely, each node is connected to all the nodes in the previous layer. The connections, shown here simply as lines, in an actual neural net comprise weighting functions \( w_i \) and the result of the computation of any node at level \( L_i \) is given here in Equation (3):

\[
L_i = T_j \sum_j w_j L_{j,i-1}
\]

or, in words, the weighted sum \( w_j \) of the \( j \) outputs of the previous \( (i-1) \) layer, multiplied by the transfer function of the layer. Thus, the calibration algorithms examined above can all be seen to be special cases of the neural net concept, in that if the hidden layer were removed, the neural net would degenerate to one or another of the various modeling methods discussed earlier, depending upon the calculations included in the output nodes. For example, if the transfer function of the output layer computes the square of the errors, the minimizing of the sum-squared difference and limiting the wavelength set becomes the recipe for the MLR algorithm. Commonly, the transfer function is a sigmoid, which thus causes the result of the node to vary between zero and unity, depending on the result of the computation of the weighted sum.

Clearly there is room for much flexibility here. Simply by changing the transfer function to something other than minimizing the sum-squared-error, completely different types of model generation algorithms can be specified, even without a hidden layer. The inclusion of a hidden layer (or layers), then, immensely increases the potential for creating models to characterize any sort of data. Research is ongoing to determine the effects that can be achieved, and also to characterize the pitfalls encountered using this methodology.

One pitfall which everyone seems to agree on is that it is very easy to overfit the data.

Sensitive and selective qualitative tests based on chemical reactions using small amounts of complex and reagents are referred to as “spot tests”. The target is to reach the utmost sensitivity and selectivity with a minimum of physical and chemical operations.

Rapid advances in spectral, chromatographic, nuclear, mass spectroscopic and electroanalytical research have changed analytical chemistry spectacularly and developed highly sophisticated analytical tools. At the same time another development has taken place in certain distinct areas of application in exactly the opposite direction. This is the search for simple, compact and inexpensive analytical devices for semiquantitative evaluation of certain elements or compounds where such approximate evaluation has diagnostic value at least in the first stage of examination.

Major manufacturers of chemical reagents concentrated their efforts mainly in a number of applicative areas, namely clinical analysis, forensic tests, air and water quality control (QC) tests and soil and food QC tests.

It must be emphasized that the applicability of spot test methodology is limited and for the exact determination of chemical substances, complex analytical procedures are unavoidable. Although the use of spot and screening tests is marginal, the margin, however, is quite significant.

1 INTRODUCTION

Spot tests are defined as an analytical technique that enables the analyst to accomplish satisfactory semimicro and ultramicro tests with simple equipment in a minimum time. The target is to reach the utmost sensitivity and selectivity with a minimum of physical and chemical operations, and the procedure must be as simple as possible.

The modern systematic development of spot test methods occupied Fritz Feigl\(^1,2\) for half a century in Vienna and Rio de Janeiro, but analytical chemists have long used single chemical tests on filter paper. These are the indicator papers for the detection of an excess of hydrogen or hydroxy ions, potassium iodide–starch paper for chlorine detection, silver carbonate-impregnated filter paper for uric acid detection, and others.

According to the writings of Pliny the Elder, the early Romans detected iron in vinegar by means of a reagent paper prepared by soaking papyrus in an extract obtained from gall nuts.

In parallel with the trend towards instrumental sophistication using the phenomenal development of microprocessors, a trend towards simplification was seen in some marginal selected areas in the form of simple, rapid and inexpensive spot and screening tests.\(^3\) Commercial companies sell vast numbers of compact spot-test systems in which the goal is the rapid establishment of the presence or absence of certain materials. It would be wasteful to devote resources to attaining precision or accuracy several magnitudes beyond that necessary in clinical urine analysis, for example, when pathological changes in the composition of urine are evidenced by a simple test. A new look was taken at the classical tests; sometimes they were refined and sometimes new ones were elaborated. In most of the tests the human eye was used as a detector; others employed simple reflectometric instruments and UV
(ultraviolet) lamps. Most commercial companies nowadays concentrate their efforts in the following applicative areas: clinical, forensic, soil and plant, air, water and food QC tests, because of the vast number of screening tests needed in these areas.

2 TECHNIQUES AND EQUIPMENT

2.1 Techniques

Spot-test procedures are the ultimate in simplicity. Classical tests are ordinarily run by using one of the following techniques:

- by bringing together one drop each of the test solution and reagent on porous or nonporous supporting surfaces such as paper, glass or porcelain;
- by placing a drop of the test solution on a medium impregnated with appropriate reagents;
- by subjecting a drop of reagent or a strip of reagent paper to the action of liberated gases from a drop of the test solution or from a minute quantity of the solid specimen.

Commercial companies produce strips of absorbent cellulose, one end of which is impregnated with the dry reagent system. These strips are mainly used in clinical, chemical and water analysis systems. The impregnated reagent area is sometimes covered with a semipermeable membrane to prevent staining by a colored matrix such as blood. Another form of reagent system is a stable compact reagent tablet, which can contain several compatible agents such as buffers and sequestering agents. Test strips for body-fluid analyses are prepared in a modern technique by printing liquid-absorbing substances on a support, drying the treated support and applying reagents to the film formed on the support. Simple color comparing devices may be part of commercial test systems. Some are calibrated color charts printed on the container, others are colored cubes molded of acrylic plastic and matched to laboratory standards. A series of nonfading glass color standards mounted on a circular disc may be used in a comparator box or continuous color discs may be applied for visual comparison.

For the semiquantitative testing of airborne contaminants in a workroom atmosphere, the detector tube technique has gained ground. The reagent system placed into the tube consists of supporting material impregnated with the chromogen selective for the air contaminant. The technique of separation of small water-soluble molecules from high-molecular-weight proteins by a semipermeable layer is utilized in the routine and simple screening test for glucose and urea in blood.

2.2 Equipment

The amount and type of equipment needed is relatively small. It is most important to have an ample supply of reagents immediately available. Balances, UV lamps, centrifuges, dryers, ovens, furnaces and a hood can be considered to be essential in the spot-test laboratory. Assorted sizes of beakers, volumetric flasks, Conway cells, crystallizing and evaporating dishes, filter sticks, separation funnels, extraction pipets, fritted glass crucibles, graduated cylinders, vials, test tubes, centrifuge tubes, cover glasses, white and black spot plates, porcelain crucibles and platinum dishes are standard for many spot-test operations. Tweezers and spatulas, microburners, blow torches, sand and water bath are essential, too.

3 SELECTED TESTS IN INORGANIC ANALYSIS

The sample should be subjected to preliminary tests before beginning a systematic search, although it is often possible to carry out conclusive tests with as little as one drop of dilute sample solution, even though considerable concentrations of other substances are present.

3.1 Examples of Preliminary Tests

A first test is carried out by heating the solid sample in contact with air in a microcrucible. If the sample’s color and structure remain unaltered, it shows the absence of volatile compounds, e.g. absence of ammonium and mercury salts, carbonates, organic compounds, water of crystallization. If the sample melts, it is an indication of the possible presence of nitrates, nitrites, carbonates, formates, chlorates, silver chloride and bromide and fusible organic compounds. If the sample chars, it is a sign of the presence of organic materials, organometallic compounds or metal salts of organic acids. If the sample changes color without charring, it shows the presence of certain heavy metal salts, such as cupric salts which are oxidized to black cupric oxide, and cadmium salts which are oxidized to dark-brown cadmium oxide. Lightening of the color may indicate the decomposition of higher oxides, e.g. lead dioxide to lead oxide, or oxidation of sulfides, e.g. lead sulfide to lead sulfate.

A second test is carried out by heating the solid sample in an ignition tube. If the sample gives off water, the presence of salts containing water of crystallization, metal hydroxides and oxyhydrates and ammonium salts of organic materials are indicated. If litmus paper detects acidic vapors, it shows the presence of acid salts or heavy-metal sulfates or sulfites.

If alkaline vapors are detected by litmus paper, ammonium salts of heat-stable nonoxidizing acids or
complex metal amines might be present. If a white sublimate appears, it indicates the presence of ammonium salts of volatile materials, As$_2$O$_3$, Sb$_2$O$_3$, or mercury salts of volatile acids or oxalic acid. The appearance of a yellow sublimate is a sign of the presence of As$_2$O$_3$, As$_2$O$_5$, HgI$_2$ or free sulfur. If a gray sublimate shows up, it might be a sign of metallic mercury derived from mercury compounds or of free arsenic. Yellow or brown vapor might show bromine derived from bromide in the presence of oxidizing agents, or nitrogen oxide derived from nitrate or nitrite, or chromyl chloride provided by dichromate and chloride. Colorless vapors show up when CO$_2$ derives from carbonates, CO derives from oxalate and formate. HCN derives by thermal decomposition of silver, mercuric or palladium cyanides, H$_2$S derives from water-containing sulfide or thiosulfate or NH$_3$ derives from ammonium salts and so on.

3.2 Tests for Cations

A few selected examples are described here. The selection is based on the simplicity of execution, on the selectivity and on the sensitivity of the reagents. The short description here might be enough to allow the tests to be carried out, but Feigl and Anger$^{11}$ should be consulted for more detail and a deeper understanding of the reactions.

**Aluminum** ions form a lake stable to acetic acid with quinalizarin. The test solution is placed on the reagent paper (filter paper soaked in 10 mg reagent dissolved in 2 mL pyridine + 20 mL acetone) and held over concentrated NH$_3$ until the initial blue color disappears. Visible change: a remaining red-violet color. Sensitivity: 0.005 µg aluminum. Interference: Be$^{2+}$.

**Ammonium** ions liberate volatile NH$_3$ by adding alkali to them in gas-evolving test tubes. A strip of moist red litmus paper is hung on the hook of the tube, which is closed and warmed to about 40°C for 5 min. Visible changes: blue color. Sensitivity: 0.01 µg ammonia. Interference: cyanides.

**Antimony** ions reduce phosphomolybdic acid to molybdenum blue. A drop of the test solution is placed on filter paper impregnated by 5% aqueous reagent and held over steam. Visible change: blue coloration. Sensitivity: 0.2 µg antimony. Interference: stannous ions.

**Arsenic** ions when oxidized to arsenate form an insoluble compound with silver ions. The test solution is warmed in a microcrucible with a few drops of ammonia and 10% H$_2$O$_2$, then acidified with acetic acid and 1% AgNO$_3$ added. Visible change: red-brown precipitate. Sensitivity: 6 µg arsenious acid. Interference: the test is specific in the absence of chromates and ferricyanides.

**Barium** ions form an insoluble salt with sodium rhodizonate solution. To a drop of the neutral or slightly acid test solution on filter paper is added 0.2% aqueous reagent (freshly prepared) dropwise. Visible change: red-brown stain. Interference: bivalent heavy-metal salts must be absent. Sensitivity: 0.25 µg barium.

**Beryllium** ions give red-violet color lake with chromeazurolone. One drop of the test solution is treated with a drop of 2N sodium acetate and one drop of the alcoholic reagent solution. Visible change: red-violet color. Sensitivity: 0.3 µg beryllium. Interference: Fe, Al, Zn and copper salts must be masked.

**Bismuth** ions form insoluble double iodide with univalent organic bases, among them cinchonine. Slightly acidic test solution is dropped on filter paper impregnated with the reagent solution (1 g cinchonine dissolved in 100 mL water containing a little nitric acid, by warming: after cooling, 2 g potassium iodide is added) Visible change: orange-red stain. Interference: from lead, copper and mercury can be avoided by zone precipitation.

**Cadmium** ions are precipitated with ferrous dipirydidyl iodide, a compound in which both the cation and the anion are large complexes. A drop of the test solution is treated with a drop of the reagent solution. Visible change: red precipitate. Sensitivity: 0.05 µg cadmium. Interference: mercury and nickel ions. The reagent solution is prepared as follows: 0.25 g α,α'-dipyridyl and 0.146 g FeSO$_4$·7H$_2$O are dissolved in 50 mL water, then 10 g KI are added, and after vigorous shaking any solids remaining are filtered off.

**Chromium** ions form colored inner complex salts with glyoxal-bis(2-hydroxynil), which are stable against alkali carbonate and extractable in chloroform. A drop of the test solution is treated successively in a test tube with 3–4 drops of the reagent solution, one drop of 10% NaOH, one drop of 10% Na$_2$CO$_3$ and 3–4 drops of chloroform. Visible change: red color in the chloroform layer. The test is specific for calcium. Although barium and strontium ions form a red complex with the reagent, they are not extractable with chloroform. Sensitivity: 0.05 µg calcium.

**Chromium** ions that are oxidized to chromate react with diphenyl carbazide and form an inner complex salt in which both the cation and the anion are large complexes. A drop of the test solution is mixed on a spot plate with a drop of saturated solution of potassium persulfate and a drop of 2% AgNO$_3$ solution and allowed to stand for 2–3 min. By adding a drop of 1% alcoholic diphenylcarbazide solution, a violet to red color is formed. Sensitivity: 0.8 µg chromium. Interference: Mo, Hg, V.

**Cobalt** ions form a series of cationic and anionic complexes with thiocyanates in the presence of ethyl alcohol or acetone. A drop of the test solution is mixed with a few drops of saturated acetone solution of ammonium thiocyanate on a spot plate. Visible change: green to blue color. Sensitivity: 0.5 µg cobalt. Interferences: Cu$^{2+}$ and Fe$^{3+}$, which can be avoided by removal of copper through precipitation in the form...
of cuprous thiocyanate by adding reducing agents, and complexing iron with fluoride, respectively.

Copper ions are precipitated with rubeanic acid (dithio-oxamide). A drop of the neutral test solution is placed on filter paper, held over ammonia and treated with a drop of 1% alcoholic solution of rubeanic acid. Visible change: black or olive-green color. Sensitivity: 0.06 µg copper Interferences: Ni²⁺, Co²⁺, Fe³⁺, Ag⁺, Bi³⁺, Pt²⁺, Pt⁴⁺. All these interferences are avoided by complexing them with 20% malonic acid and 10% ethylenediamine.

Gold ions (tervalent) are easily reduced to metallic gold with strong reducing agents. Filter paper impregnated with stannous chloride is dried at not more than 40°C for 2h. On adding a drop of a solution containing gold, violet-colored metallic gold forms. Sensitivity: 1 µg gold.

Iron (bivalent) ions give a stable complex cation with a,α'-dipyriddy. A drop of the test solution is placed on filter paper which has been impregnated with a 2% solution of the reagent in thioglycolic acid. The latter reduces tervalent iron. Visible change: red color. Interferences: considerable quantities of cobalt and nickel ions. Sensitivity: 0.03 µg iron.

Lead ions are precipitated as chelates with dithizone. A drop of the test solution is shaken in a test tube with the reagent dissolved in carbon tetrachloride. Visual change: red color. Sensitivity: 0.04 µg lead. Interferences: heavy metal ions disturb, but complexing with alkali tartrate and cyanide [CARE], makes the identification of lead specific.

Magnesium ions give a blue lake with quinalizarin in alkaline solutions. A drop of the test solution and a drop of distilled water are placed in adjoining depressions in a spot plate and mixed with 2 drops of an alcoholic 0.02% solution of the reagent. 2N NaOH solution is added drop by drop until a change to violet occurs. Visual change: a blue precipitate in comparison with the violet blank. Sensitivity: 0.25 µg magnesium. Interferences: La, Be, Nd, Pr, Ce, Zr and Th.

Manganese ions are oxidized catalytically to violet permanganates. A drop of the test solution is mixed with a drop of concentrated sulfuric acid in a microcrucible. A drop of 0.1% silver nitrate solution is stirred in, followed by a few milligrams of ammonium persulfate. The mixture is gently heated. Visual change: red-violet color. Sensitivity: 0.1 µg manganese. Interference: halides should be absent.

Mercuric ions form a red cuprous mercuric iodide complex with a white suspension of cuprous iodide. The acidic test solution (pH = 0) is treated on filter paper with a drop of potassium iodide (5%)–sodium sulfite solution (20%), followed by a drop of 5% CuSO₄ solution. Visual change: red or orange color. Sensitivity: 0.003 µg mercury. Interferences: Ag⁺, Hg₂²⁺, Au⁺³, Fe³⁺, Ce⁴⁺. All interferences might be avoided by a pretest treatment.

Molybdenum (tervalent) ions produce a red watersoluble H₃[Mo(CNS)₆] complex. A drop of the test solution and a drop of 10% potassium thiocyanate solution are placed on filter paper previously moistened with 1:1 hydrochloric acid. In the presence of ferric iron, a red stain appears which disappears when adding 5% stannous chloride in 3N HCl. In the presence of molybdate, a brick red Mo³⁺–thiocyanate complex forms. Sensitivity: 0.1 µg molybdenum.

Nickel ions form a red chelate with dimethylglyoxime. A drop of the test solution and one drop of 1% alcoholic reagent solution are placed on filter paper and held over ammonia. Sensitivity: 0.16 µg Ni. Interferences: large amounts of oxidizing substances. Pd gives an analogous yellow chelate.

Palladium(II) ions form an acid-insoluble yellow chelate on the surface of red nickel dimethylglyoxime paper. This layer protects the underlying red compound against dissolution in acid. A drop of the test solution is placed on the reagent paper and almost dried by gentle warming. The paper is then bathed in dilute HCl. The red compound dissolves except for the palladium protected spot. Visual change: a red fleck remains. Reagent paper preparation: filter paper is bathed in cold saturated alcohol solution of dimethylglyoxime. After drying, the paper is placed in 2N Ni(NO₃)₂ solution made ammoniacal. The paper is washed with alcohol. Sensitivity: 0.05 µg palladium.

Platinum(IV) salts, like those of gold, palladium and osmium in acid solution, are reduced to the elementary state by stannous chloride using the following procedure. The platinum can be detected even in the presence of these other noble metals. A drop of saturated thallium nitrate solution is placed on filter paper, followed by a drop of the test solution and another drop of TlNO₃ solution. The paper is washed with ammonia. Tl₂[PtCl₆] remains on the paper only. A drop of stannous chloride solution in strong HCl is added. Visual change: orange-red stain. Sensitivity: 0.025 µg platinum.

Potassium ions are precipitated with sodium tetraphenylboron. The test is particularly valuable if potassium is to be detected in the presence of a lot of sodium. A drop of the test solution is placed on a black spot plate with a drop of a 2% water solution of the reagent. Visual change: white precipitate. Sensitivity: 1 µg potassium. Interferences: NH₄⁺, Cs⁺, Rb⁺, heavy metal ions.

Silver ions are precipitated with manganese salts and alkali, as MnO₂ and metallic silver. Both are black. Since mercurous salts, noble metals and stannous salts react analogously, AgCl should be isolated beforehand in order to prevent such interferences. A drop of 0.1N HCl is placed on a filter paper followed by a drop of the test solution and then a further drop of HCl. The fleck is
blackened at the addition of a drop of 0.1 N manganese nitrate and a drop of 0.1 N NaOH. Sensitivity: 2 µg silver.

Sodium ions impart a characteristic yellow color in the flame. This flame test is extremely sensitive, so even omnipresent sodium traces are detectable. A sodium concentration of as little as 0.01 ppm yields a very persistent and intense yellow coloration in the flame.

Strontium ions react in neutral solution with sodium rhodizinate and form a brown-red precipitate. To detect Sr in the presence of Ba, the latter must be converted first to insoluble sulfate. The solubility of SrSO₄ allows its detection with rhodizonate. A drop of the test solution is placed on filter paper impregnated with saturated sodium sulfate solution and the sulfates are formed. After a minute, a drop of freshly prepared 0.2% reagent solution is placed on the spot. Visible change: brown-red precipitate.

Tin(II) ions reduce ammonium phosphomolybdate (in contrast to molybdenum blue). Filter paper impregnated with an aqueous 5% phosphomolybdic acid solution is held over ammonia until an insoluble yellow material forms on the reagent paper. Quadrivalent tin must be reduced with a tiny piece of zinc and a few drops of concentrated hydrochloric acid. Visual change: deep blue color. Sensitivity: 0.03 µg tin.

Tungsten(VI) ions are precipitated as a white amorphous product with 2,4-diaminodiphenyl hydrochloride. A drop of the test solution is mixed in a microtest tube with a 1% solution of the reagent in 2 N HCl. Sensitivity: 6 µg tungsten. Interference: molybdates disturb in concentrations larger than 10%.

Uranium(VI) ions fluoresce in crystalline form, but only slightly in solution. Sodium fluoride beads of uranyl salts are most striking and are used to detect uranium. Sodium fluoride is fused in a loop of platinum wire. A neutral test solution is placed on the bead and evaporated slowly. After fusing for a short time, the bead is cooled and examined in UV light. Visual change: deep yellow fluorescence. Sensitivity: 0.001 µg uranium. Interferences: only niobium and beryllium give a much weaker similar fluorescence.

Vanadium(V) as the vanadates forms a yellow precipitate in strongly acidic solution with α-benzoinoxime. Analogous white compounds are formed with the same reagent by molybdates and tungstates. Two drops of the saturated reagent solution in ethyl alcohol are added to a drop of the test solution followed by a drop of 3 N H₂SO₄. Sensitivity: 1 µg vanadium. It is a specific reaction, only the color of Fe³⁺ might interfere. This can be avoided by adding phosphate.

Zinc ions raise the oxidation potential of the ferrocyanide and removing ferrocyanide ions from the redox equilibrium between ferricyanide and 3,3'-dimethylphthalhydride. A drop of the reagent solution (freshly prepared mixture of one part 5% solution of potassium ferricyanide in water and two parts saturated aqueous solution of 3,3'-dimethylphthalhydride chloride) and a drop of weakly acid test solution are brought together on a spot plate. Visual change: red-violet color. Sensitivity: 0.1 µg zinc.

Zirconium(IV) ions with morin form a pale-yellow, acid-resistant color in daylight and a yellow-green fluorscencing lake in UV light. A drop of the test solution is mixed on the spot plate with a drop of 0.001% reagent solution in ethyl alcohol and some drops of concentrated HCl. Sensitivity: 0.1 µg zirconium. Interferences: it is a specific reaction but cupric, ferric, vanadate, chromate and noble-metal ions quench the fluorescence.

3.3 Selected Tests for Anions

If the original material does not consist solely of alkali salts, the sample is boiled with strong sodium carbonate solution or is fused with sodium potassium carbonate in a platinum spoon. Heavy-metal salts are thus converted in water-insoluble carbonates. The only soluble metal carbonate, except for the alkali carbonates, is Tl₂CO₃. Spot reactions to detect the various anions can be successfully made on drops of the sodium carbonate extract. Acetic acid is added to the carbonate extract until no further carbon dioxide evolves.

Borates can liberate free boric acid which gives a deep red compound when evaporated with tincture of curcuma (turmeric). The boric acid changes the yellow curcumin into the isomeric red-brown rosocyanine. A drop of the test solution acidified with HCl is placed on curcuma paper and dried at 100°C. Visual change: a red-brown fleck, which turns blue to greenish-black on treatment with 1% NaOH. Sensitivity: 0.02 µg boron. Interferences: oxidizing substances (H₂O₂, CrO₄²⁻, NO₂⁻, ClO₃⁻ and iodides). They must be decomposed before carrying out the reaction.

Chloride ions are detected in the presence of other halide ions by selective oxidation of bromides and iodides and halogenating 8-hydroxyquinoline with the halogen. Chlorides are not oxidized and are precipitated with AgNO₃ solution. A drop of the test solution is warmed with a drop of 2% reagent in 1:4 acetic acid and a drop of H₂O₂ solution (2 parts of 6% H₂O₂ and 1 part dilute CH₃COOH). A drop of 1% AgNO₃ solution is added. Visual change: white precipitation.

Cyanide ions can be converted to thiocyanate, which is detected by the sensitive iron reaction. A drop of the test solution is stirred with a drop of yellow ammonium sulfide on a watch glass and warmed until a rim of sulfur is formed around the liquid. After the addition of some
dilute HCl, 1–2 drops of 1% FeCl₃ are added. Visual change: red color. Sensitivity: 1 µg cyanide. Interference: in the presence of thiocyanates, the cyanide should be first isolated as Zn(CN)₂.

**Ferrocyanate**, thiocyanate and *thiosulfate* anions are detected simultaneously by capillary separation of their respective ferric compounds. Filter paper is impregnated with ferric chloride solution and dried. The paper is spotted with dilute HCl and then with the test solution. After a short time, individual colored areas are observed due to capillary separation. From the center outward they reveal: ferrocyanide, blue fleck; thiosulfate, white ring; thiocyanate, red ring. The sensitivities of the detections depend on the ratio of the three components but they are lower than 1 µg each.

**Iodide** ions react with palladous chloride to form a brown-black precipitate of PdI₂. The latter is insoluble in mineral acids but soluble in ammonia, NaCl and MgCl₂. A drop of the test solution is spotted on filter paper with a drop of 1% reagent Sensitivity: 1 µg iodide.

**Nitrate** ions oxidize diphenylamine to blue quinoid imonium dye. About 0.5 mL of the strongly acid diphenylamine solution is placed on a spot plate, and in the middle a drop of the test solution is added. Sensitivity: 0.5 µg nitrate. Interferences: alkali halogenates, perchlorates, periodates, permanganates, persulfates, peroxides and nitrites. The interferences of the six anions can be averted by drying the sample and heating the residue to 400°–500°C. All but the nitrate and nitrite are decomposed. Sulfamic acid, on the other hand, destroys the nitrite in advance.

**Nitrite** ions form diazonium cations with primary aromatic amines in acid solution which couple with the same (or with another) primary aromatic compound and result in colored azo compounds. A drop of the test solution is mixed on a spot plate with a drop each of 1% sulfanilic acid in 30% acetic acid and a 0.03% solution of *p*-aminodimethylaniline. Visual change: red fleck; thiocyanate, white ring; thiosulfate, red ring. The sensitivities of the detections depend on the ratio of the three components but they are lower than 1 µg each.

**Phosphate** ions react with molybdates forming complex phosphomolybdic acid. The latter has an enhanced oxidizing power, oxidizing tetrabase to its blue quinoidal compound. A drop of the acid test solution is placed on the quantitative filter paper followed by a drop of ammonium molybdate solution (5 g salt dissolved in 100 mL water and poured into 35 mL HNO₃ specific gravity 1.2) and a drop of saturated tetrabase solution in 2 N CH₃COOH. Sensitivity: 0.05 µg phosphate. Interferences: germanic, arsenic and silicic acids behave analogously.

**Silicate** ions form the complex silicomolybdic acid H₂SiO₄, 12MoO₃ when treated with molybdate. It is reduced by sodium stannite solution to molybdenum blue. Three drops of ammonium molybdate solution is placed on a watch glass followed by a drop of the test solution and a drop of alkali stannite solution Visual change: blue color. Sensitivity: 1 µg SiO₂. Interferences: phosphoric and molybdic acid.

**Sulfate** ions decompose the red-brown precipitate of barium rhodizonate by forming insoluble BaSO₄. A drop of BaCl₂ is placed on filter paper followed by a drop of freshly prepared 0.2% solution of sodium rhodizone. The red fleck is treated with a drop of the test solution Visual change: the red fleck disappears. Sensitivity: 5 µg SO₄²⁻.

**Sulfide** ions form methylene blue with *p*-aminodimethylaniline and FeCl₃. H₂S is liberated from the test solution and absorbed by glass fiber paper moistened with dilute NaOH. Add a mixture of a drop each of concentrated HCl, 0.1 N FeCl₃ and several granules of *p*-aminodimethylaniline. Visual change: blue. Sensitivity: 1 µg sulfide.

### 4 SELECTED TESTS IN ORGANIC ANALYSIS

The main field of qualitative organic analysis is in the detection of certain groups of compounds, the detection of characteristic types of compounds and, whenever possible, the identification of individual compounds. These goals are mainly attained through observation of the results of the chemical reactions into which the functional group enters. Such reactions include chelate formation, catalyzed and induced reactions, masking procedures, solid–solid reactions at elevated temperatures, reactions in the gas phase through contact with solid or dissolved reagents and reactions which yield fluorescent or colored products or those which fluoresce.

These qualitative tests⁴ are instrumentally unsophisticated but their use has considerable practical importance. Analytical problems seldom involve totally unknown materials. The information available concerning the origin, method of preparation, color of the sample and so on, almost always gives valuable clues as to the direction of the spot-test examination. The analytical problem is not always to detect a particular organic compound, but rather to find out whether members of the class are present or absent.

#### 4.1 Preliminary Tests

##### 4.1.1 Sensory Tests (Color and Odor)

As most pure organic compounds are colorless and odorless, the appearance of color and odor has some limited diagnostic value. Yellow material can indicate nitro, nitroso and azo compounds, and a shift to a longer wavelength might suggest the presence of conjugation, chelation or dyestuffs. Fluorescence is indicative also,
but only in material carefully purified by sublimation or recrystallization.

The detection of odoriferous materials such as menthol, phenol, pyridine, butyric acid and vanillin can be extremely sensitive. Nitrobenzene and benzaldehyde have an almond odor, ethyl sulfide has a garlic and long-chained fatty acids have characteristic rancid odors.

4.1.2 Burning Tests

Different visual phenomena appear by ignition of various classes of organic compounds under similar conditions. Burning aromatic compounds and halogen compounds furnish a smoky flame whereas the lower aliphatic compounds burn with a smokeless flame. Compounds containing a high percentage of halogen do not ignite easily and oxygen-containing compounds show a bluish flame. Proteins and carbohydrates burn with an odor resembling burnt hair.

4.1.3 Pyrolysis

Rapid external heating generally leads to the formation of lower-molecular-weight compounds, which can be detected in the gas phase. The latter are HCN, (CN)$_2$, hydrogen halides, acetaldehyde, CO, SO$_2$, nitrous oxide, phenols and so on. HCN appears in the gas phase by pyrolysis of nitrogenous organic material. The detection of (CN)$_2$ is almost specific for uric acid in the gas phase. The latter are HCN, (CN)$_2$, hydrogen halides, acetaldehyde, CO, SO$_2$, nitrous oxide, phenols and so on. HCN appears in the gas phase by pyrolysis of nitrogenous organic material. The detection of (CN)$_2$ is almost specific for uric acid.

4.1.4 Acid–Base and Redox Behavior

The basic or acidic behavior of a material can afford a valuable clue in the detection of basic or acidic functional groups. The derivatives of ammonia, hydroxylamine and hydrazine are bases, whereas functional groups which split hydrogen ions, such as carboxylic, sulfonic, sulfinic, arsionic, nitroxylic, oxinic, thioenolic, phenolic and thiophenolic are detectable by acid character. For water-soluble compounds, conventional indicators would be useful, whereas for water-insoluble compounds, basic groups are detected by shifting of the reaction equilibrium of nickel with dimethylglyoxime. After removal of the precipitate, the equilibrium solution which results may react with the basic unknown and the consumption of protons will lead to the appearance of the red precipitate. On the other hand, extremely weak organic acids heated with prefused potassium iodate (which contains iodide) leads to iodine liberation.

Organic reductants are indicated by a molybdenum blue reaction, whereas a preliminary test with tetrabase reagent paper might detect the few classes of oxidizing compounds, such as polyhalides of organic bases, quinones and peroxyacids.

4.1.5 Elemental Analysis

The organic material is pyrolyzed with carbonates, strong oxidizing acids, oxidants such as vanadium pentoxide or heated in aluminum foil under a stream of oxygen. For details, consult Feigl and Anger.\(^{(1)}\)

4.2 Selected Tests for Functional Groups

An organic molecule may include several of such groups and their detection may largely characterize its chemical and physical properties. The most common functional groups are discussed here.

Aromatic compounds react with concentrated H$_2$SO$_4$ containing formaldehyde and form red, green and violet precipitates. The reaction occurs only when the para position is free. This enables the formation of methylene compounds, which are partly oxidized to p-quinoidal compounds. A drop of the nonaqueous test solution or a little of the solid is treated on a spot plate with a drop of formaldehyde–sulfuric acid reagent (0.2 mL of 37% formaldehyde in 10 mL concentrated H$_2$SO$_4$). Sensitivity: 2–25 µg aromatics.

Primary, secondary and tertiary alcohols convert $\text{[Ce(NO}_3)_6\text{]}^{2-}$ into $\text{[Ce(OR)(NO}_3)_5\text{]}^{2-}$ with a color change from yellow to red. The reagent solution is 40% $\text{[NH}_4\text{]}_2\text{Ce(NO}_3)_6$ in 2 N HNO$_3$. One millilitre of the reagent solution diluted with 2 mL of dioxane is treated with the test solution. Sensitivity: 400 µg alcohol. Interferences: aliphatic bases and oxidizable compounds.

Secondary alcohols fused with sulfur release H$_2$S on heating. In a microtest tube, the test solution is treated with a drop of 2% sulfur solution in carbon disulfide and dried. The mouth of the tube is covered with a disc of lead acetate paper and placed in a glycerol bath previously heated to 150 °C. Visual change: appearance of black lead sulfide on the paper. Sensitivity: 10–200 µg alcohol.

Volatile phenols condense with 2,6-dichloroquinone-4-chloroimine to give colored indophenols. A drop of the test solution is dried in a test tube. The mouth of the tube is covered with a disc of filter paper impregnated with a saturated benzene solution of the reagent. The tube is placed in a glycerol bath preheated to 150 °C. The reagent paper is held in NH$_3$ vapos. Visual change: blue stain. Sensitivity: 0.3–20 µg phenol.

Phenols react with nitrous acid containing mercuric nitrate to form nitro compounds reacting with the phenol.
A drop of the test solution is mixed in a microcrucible with a drop of the reagent solution (one part mercury is dissolved in one part of fuming HNO₃ and diluted with two parts of water). Visual change: red color. Sensitivity: 0.5–10 µg phenol. Note: di-o- and di-m-substituted phenols do not react.

Aromatic and aliphatic aldehydes condense with primary aromatic amine forming colored Schiff bases. Dianisidine is an especially suitable reagent for this. A drop of the sample is mixed with 3–4 drops of the saturated solution of the reagent in glacial acetic acid. The light color is intensified on heating. Sensitivity: 0.05–50 µg aldehyde. Interference: large amounts of certain ketones.

Aromatic aldehydes condense with N,N-dimethyl-p-phenylenediamine to give an intensely red protonated Schiff base. Several milligrams of the solid oxalate or chloride of the reagent are added to a drop of the test solution in a microtest tube and warmed in a preheated water bath. Aliphatic aldehydes and ketones do not interfere. Sensitivity: 0.3–0.5 µg aldehyde.

Aliphatic ketones react with m-dinitro compounds in alkaline solution to yield violet products. The reaction is selective for aliphatic monoketones. A drop of a 1% solution of m-dinitrobenzene in alcohol is mixed in a microtest tube with a saturated methanolic solution of KOH and a drop of the test solution. The tube is warmed to 70–80 °C in a water bath for 2–3 min. Visual change: violet-red color.

Carboxylic acids are converted via acid chloride into hydroxamic acids. The latter react with ferric ions to give a red or bluish-red chelate. A drop of the test solution is evaporated to dryness in a microcrucible and treated with two drops of thionyl chloride. The mixture is evaporated almost to dryness. Two drops of saturated alcoholic solution of hydroxylamine hydrochloride are then added and made basic with alcoholic alkali. The mixture is acidified with 0.5 N HCl and treated with 1% aqueous FeCl₃ solution. Visual change: dark-violet. Sensitivity: 10–100 µg carboxylic acids. Interferences: citric and thioacetic acid.

Alkyl esters of carboxylic acids react with metallic sodium to form acyloliths. The latter is identified by its reaction with 1,2-dinitrobenzene to produce the red acid form of nitrosonitrobenzene. The test is conducted in the depression of a spot plate. A small piece of metallic sodium (CARE) is pressed into a disk with a glass rod. A drop of a benzene solution of the test material is added and then a drop of 2.5% benzene solution of 1,2-dinitrobenzene. The system is stirred with a glass rod and a drop of water is introduced. Visual change: deep-violet color.

Ethers are oxidized at higher temperatures (230 °C) to etherperoxides which oxidize, via cupric peroxide, tetrabase to tetrabase blue. A drop of the test solution is placed in a microtest tube. The tube is plunged into a glycerol bath preheated to 230 °C. The mouth of the test tube is covered with a disc of filter paper moistened with a mixture of 5% aqueous copper ethylacetooxacetate and 5% chloroform solution of tetrabase. Sensitivity: 20 µg diethylether.

Interferences: the test fails in the presence of benzene and CS₂. However, it is also given by dioxan and tetrahydrofuran; it seems that the –CH₂–O–CH₂ group is responsible for the auto-oxidation.

Aromatic primary amines react with Na₂[Fe(CN)₅-ArNH₂] and produce bluish-green Na₂[Fe(CN)₅ArNH₂]. A drop of the test solution is mixed with a drop of 1% reagent and a drop of 2% Na₂CO₃ solution on a spot plate. Sensitivity: 0.2–50 µg amines.

Primary and secondary aliphatic and aromatic amines condense with p-dimethylaminocinnamaldehyde to yield colored Schiff bases. A drop of saturated solution of the reagent dissolved in methanol and trichloroacetic acid is placed on filter paper and treated with a drop of the test solution. The filter paper is kept in an oven at 100 °C for about 3 min. Visual change: blue for primary and purple color for secondary amines. Sensitivity: 0.02–2.2 µg amines.

Primary and secondary aliphatic amines form dithiocarbamates with carbon disulfide instantly at room temperatures. The dithiocarbamates can be detected by the catalytic enhancement of the sodium azide–iodine reaction. A drop of the alcoholic test solution is mixed in a microcrucible with a few drops of a 1:1 mixture of alcohol: CS₂. The excess of CS₂ is volatilized after about 5 min. A few drops of the reagent (3% Na₂S in 0.1 N iodine solution) is added. Visual change: the color of the iodide disappears and evolution of nitrogen bubbles is observed. Sensitivity: 1–250 µg amines. Interferences: mercaptans, thio ketones and thiol compounds. Tertiary aliphatic amines do not react.

Aliphatic secondary amines form blue-violet compounds reacting with sodium nitroprusside and acetaldehyde in alkaline solution. Primary and tertiary amines do not interfere. A drop of the test solution is mixed with a drop of the reagent (freshly prepared 1% solution of sodium nitroprusside to which 10% acetaldehyde is added.) The mixture is made basic with a 2% solution of sodium carbonate. Visual change: blue-violet color. Sensitivity: 1–100 µg amine. Interference: disopropylamine does not react.

Nitro compounds added to molten tetrabase (melting point 91 °C) lead to yellow-orange-red melts, molecular compounds are obtained between the two components. One drop of the ethereal or benzene solution of the sample and one drop of 5% benzene solution of the reagent are mixed in a microconical tube and dipped into boiling water. Visual change: after evaporation of the solvent, a
yellow-orange melt appears. Sensitivity: 0.3–50 µg nitro compound. Interference: p-quinoid compounds.

Primary aliphatic nitro compounds are pyrolytically reduced to nitrous acid when heated to 160 °C with benzoic acid. The benzene solution of the test material is brought together with some solid benzoic acid in a microtest tube. After solvent volatilization, the test tube is immersed in a glycerol bath preheated to 130 °C. The mouth of the test tube is covered with a filter paper moistened with Griess reagent (a mixture of 1% solution of sulfanilic acid and 0.1 aqueous solution of N-1-naphthylethylendiamine dihydrochloride) and the temperature raised to 160 °C. Visual change: red fleck on the reagent paper. Sensitivity: 10–20 µg nitro compounds.

Aromatic nitro compounds can be reduced with metallic zinc in weakly acidic solution to aryldihydroxylamines. The latter form violet complexes with pentacyanoammine ferrocyanuric. A few milligrams of the sample are dissolved in hot alcohol in a test tube and treated with a few drops of 10% CaCl₂. About 50 mg of zinc dust is added and the suspension is heated in a strongly boiling water bath. The filtrate is cooled and 1 drop of 1% reagent solution is added. Visual change: purple, blue or green color. Sensitivity: 0.8–15 µg nitro compound.

Nitrites (cyanides) are converted to oxamidic acid by heating with hydrated oxalic acids (pyrohydrolysis). The resulting oxamidic acid is detected by its sintering with thio-barbituric acid. A drop of the test solution is added to 0.1% of K₃Fe(CN)₆ in water) is placed over the mouth of the test tube. After solvent volatilization, the test tube is placed in a glycerol bath preheated to 230–250 °C. A disc of filter paper moistened with ferric ferricyanide solution (0.08% anhydrous FeCl₃ and 0.1% of K₂Fe(CN)₆ in water) is placed over the mouth of the test tube. Visual change: blue stain on the paper. Sensitivity: 1–20 µg sulfonic acids.

---

4.3 Detection of Individual Organic Compounds

The measurement of certain physical properties provides a very reliable method for the identification of an organic material. Determination of melting and boiling points, density of compounds and optical qualities such as refractive index, optical activity, UV and infrared (IR) absorption are very useful, but the essential requirement of isolating the compound in a state of a high purity is very costly with regard to time and material. For this reason rapid chemical identifications that do not require expensive apparatus are important. The possibility of finding a direct specific test for an individual compound is highly improbable but the available information about the origin, method of preparation and use of the material in question provide valuable clues. In fact, the analytical goal is often defined by the question of whether particular compounds are present or absent. The following section contains descriptions of selected spot tests for technically important individual compounds.

Acetone condenses with salicylaldehyde to form a red conjugated compound. One drop of 10% alcoholic solution of the reagent is mixed in a test tube with one drop of 40% NaOH solution and a drop of the test solution. The tube is kept for 2–3 min in a water bath at 70–80 °C. Visual change: deep-red color. Sensitivity: 0.2 µg acetone.

Acetic acid forms a dark-blue adsorption compound with iodine and basic lanthanum acetate when mixed with iodine and ammonia. The interference of many anions is avoided by the microdistillation of acetic acid in the presence of concentrated H₃PO₄. In the depression of a spot plate a drop of the solution is mixed with acetic acid with one drop of 0.01 N iodine solution and a drop of 1 N NH₃. Visual change: blue stain in a few minutes. Sensitivity: 50 µg acetic acid.
to its reactive $\text{CH}_2$ group, reacts with 1,2 naphthoquinone-4-sulfonate. A colored condensation product results. A drop of the test solution is mixed with some solid NH$_2$SCN and heated in boiling water for 2 min. The cooled mixture is treated with 1–2 drops of 0.5% reagent and made alkaline with 1% NaOH solution. The cooled mixture is treated with 1–2 drops of Ag$_2$CrO$_4$. It is an acid-insoluble addition compound monochloroacetic acid. (Ag$_2$CrO$_4$ dissolved in 1 : 5 NH$_3$ and filtered) is placed in silver chromate. A drop of ammoniacal silver chromate is added in the presence of acetylene a residue of red-brown Ag$_2$CrO$_4$ remains. Sensitivity: 1 µg acetylene.

$\text{Acetylene}$ forms an orange precipitate with ammoniacal Ag$_2$CrO$_4$. It is an acid-insoluble addition compound Ag$_2$C$_2$:Ag$_2$CrO$_4$ which serves as a protective layer around silver chromate. A drop of ammoniacal silver chromate (Ag$_2$CrO$_4$ dissolved in 1 : 5 NH$_3$ and filtered) is placed in each of two small porcelain crucibles. One drop of the solution being tested for acetylene is added to one of the suspensions, and a drop of water to the other. The solution being tested for acetylene is added to one of the suspensions, and a drop of water to the other. The mixtures are stirred and treated with the same number of drops of 1 : 10 HNO$_3$ until the Ag$_2$CrO$_4$ precipitate in the blank disappears. Visual change: in the presence of acetylene a residue of red-brown Ag$_2$CrO$_4$ remains. Sensitivity: 1 µg acetylene.

$\text{Anthracene}$ evaporated with concentrated HNO$_3$ is oxidized to anthraquinone, which can be detected by reductive conversion with solid sodium hydrosulfite in alkaline solution to the red water soluble salt of anthrohydroquinone. Sensitivity: 3 µg anthracene.

$\text{Ascorbic acid}$ reduces ammonium phosphomolybdic acid to molybdenum blue. A drop of the test solution is placed on the reagent paper (filter paper immersed in a saturated alcoholic solution of phosphomolybdic acid, dried in cold air, bathed in concentrated Ag$_2$CrO$_4$ solution and dried again). Visible change: blue color. Sensitivity: 0.1 µg ascorbic acid. Interference of uric acid or urate is avoided by acidifying the sample.

$\text{Barbituric acid}$ reacts instantaneously with nitrous acid to give violuric acid. A drop of the test solution is mixed in the depression of a spot plate with one drop each of 2N CH$_3$COOH and saturated NaNO$_2$ solution. Visual change: red violet. Sensitivity: 10 µg barbituric acid.

$\text{Carbon disulfide}$ forms dithiocarbamates with secondary aliphatic amines, which in turn produce chelates with transition-metal ions. In a microtest tube a drop of the test solution is treated with a drop of reagent solution (9 mL 0.2% CuSO$_4$ solution mixed with 1 mL concentrated NH$_3$ and 0.5 g dimethylamine chloride.) The tube is shaken with 2 drops of benzene. Visual change: yellow-brown color in the benzene layer. Sensitivity: 3 µg carbon disulfide.

$\text{Carbon tetrachloride}$ vapor releases chlorine when heated in the presence of quartz sand. It is most likely that a disproportionation occurs on the surface of the quartz. In a microtest tube a drop of the test solution is mixed with several centigrams of quartz dust. The tube is immersed in a glycerol bath preheated to 150°C and the mouth of the tube is covered with a disc of Congo Red paper moistened with 5% H$_2$O$_2$ solution. Visual change: blue stain. Sensitivity: 5 µg CCl$_4$. Interference: sym-dichloro(bromo)ethane and sym-tetrachloro(bromo)ethane show the same behavior.

$\text{Citric acid}$ is converted by alkali permanganate into acetone dicarboxylic acid, which in the presence of bromine precipitates as pentabromoacetone. A drop of the test solution is mixed in a microtest tube with one drop each of 0.01 N KMnO$_4$ and a drop of saturated bromine water. After cooling, the excess bromine and MnO$_2$ are destroyed with the addition of some solid sulfosalycilic acid. Visual change: white precipitate. Sensitivity: 6 µg citric acid.

$\text{Formaldehyde}$ condenses with J-acid dissolved in concentrated H$_2$SO$_4$ to produce a yellow fluorescent xanthylum dyestuff. Add one drop of aqueous test solution to a drop of a 0.1% solution of J-acid (6 amino-1-naphthol-3-sulfonic acid in concentrated H$_2$SO$_4$) on a glass filter paper. Visual change: yellow fluorescence under a UV lamp after addition of a drop of water, the yellow solution turns blue. Sensitivity: 0.01 µg formaldehyde.

$\text{Glycerol}$ is dehydrated with concentrated H$_2$SO$_4$ to acrolein, which according to the classical Skraup synthesis forms 8-hydroxyquinoline with o-aminophenol. The magnesium salt of 8-hydroxyquinoline is highly fluorescent. Two drops of 2% alcoholic solution of o-aminophenol are evaporated in a microtest tube. A drop of the test solution and 4 drops 1% arsenic acid in concentrated H$_2$SO$_4$ are added. The tube is kept at 140°C for about 15 min, and after cooling 5 drops of concentrated NaOH, 1 drop of 2N MgSO$_4$ and three drops of concentrated NH$_3$ are added. Visual change: bluish-green fluorescence. Sensitivity: 0.5 µg glycerol. Interference: crotonaldehyde.

$\text{Malonic acid}$ fused with urea forms barbituric acid. The latter is identified by its reaction with pyridylpyridinium dichloride to give a pentamethine dye. A drop of the test solution is treated with several drops of a saturated methanolic solution of urea in a microtest tube. The tube is heated for several minutes in a glycerol bath at 120°C. A drop of 1% solution of pyridylpyridinium dichloride in dimethylformamide (DMF) is added. The mixture is heated to 120°C for several minutes. Visual change: reddish-blue color develops on cooling, which shows a red fluorescence red under UV. Sensitivity: 50 µg malonic acid. The detection is specific.

$\text{Methanol}$ is oxidized by acidic permanganate to formaldehyde. The latter is detected specifically by forming a bright violet p-quinoidal compound with chromotropic acid. A drop of the test solution is mixed with a drop of 5% H$_3$PO$_4$ and a drop of 5% KMnO$_4$. The mixture is decolorized by sodium bisulfate crystals and 4 mL of 12N H$_2$SO$_4$. A little finely powdered
chromotropic acid is added and heated to 60 °C for 10 min. Visual change: violet color. Sensitivity: 3.5 µg methanol.

Naphthalene vapor reacts selectively with chloranil to give a brick-red addition compound. The solid unknown or its ethereal solution is placed in a microtest tube and the mouth of the tube is covered with a disc of filter paper impregnated with a saturated ethereal solution of chloranil. The tube is immersed in a water bath at 60 °C. Visual change: brick-red color on the paper. Sensitivity: 25 µg of naphthalene.

Oxalic acid decomposes pyrolitically at 250 °C to give formic acid, which forms aniline blue with diphenylamine. In a microtest tube a drop of the sample is evaporated and melted with a little diphenylamine over a free microflame. After cooling, a drop of alcohol is added. Visual change: blue coloration. Sensitivity: 5 µg oxalic acid.

Piperidine reacts through its reactive NH₂ group with 1,2-naphthoquinone-4-sulfonate to produce intensely colored p-quinoidal condensation products. In a microtest tube a drop of the acidic test solution is mixed with several centigrams of Na₂CO₃. The tube is immersed in a water bath heated to 90 °C and the mouth of the tube is covered with a disc of filter paper moistened with a 2.5% aqueous solution of the reagent. Visual change: red stain on the yellow paper. Under the conditions described piperazone does not disturb the detection. Sensitivity: 20 µg piperidine.

Pyridine reacts with trisodium pentacyanoamminoferrate, by replacement of the ammonia with pyridine in the coordination sphere, forming a colored compound. On a Whatman filter paper No.1, a drop of the test solution is sprayed with one drop of 0.2% solution of the reagent in buffer solution at pH 6.5. Visual change: yellow-orange coloration. Sensitivity: 10 µg pyridine.

Quinones give colored condensation products with rhodamine. A drop of the test solution is shaken with one drop of a saturated aqueous solution of the reagent and one drop of ammonia. Visual change: green or blue with p-quinones and violet-red with o-quinones. Sensitivity: 0.2–5 µg quinones.

Salicylic acid is converted easily to fluorescent alkali salicylate with dissolved alkali and alkaline-earth salts. This acid can be separated adequately by sublimation on heating the substance with concentrated H₂SO₄. A drop of the test solution is evaporated in a microtest tube. A drop of concentrated H₂SO₄ is then added and the mouth of the tube is covered with a glass-paper disc wetted with 3% KOH. The tube is heated in a glycerol bath at 130 °C. Visual change: violet fluorescence on the glass paper. Sensitivity: 5 µg salicylic acid.

Tartaric acid heated with concentrated H₂SO₄ containing β,β’-dinaphthol produces green fluorescence. The test solution is treated in a test tube with a few milliliters of 0.05% concentrated H₂SO₄ solution of the reagent and kept for 30 min in a water bath at 85 °C. Visual change: luminous green fluorescence. Sensitivity: 5 µg tartaric acid.

Thiophene condenses with ninhydrin in concentrated H₂SO₄ to give a violet dyestuff. In a depression of a spot plate one drop of freshly prepared 0.01% reagent in concentrated H₂SO₄ is covered with a drop of the test solution. Visual change: deep violet to pink color. Sensitivity: 5 µg thiophene.

Urea is quickly hydrolyzed enzymatically to ammonia even at room temperature. A drop of the neutral or alkaline test solution is treated in the depression of a spot plate with several milligrams of urease and after 2–5 min one drop of Nessler solution (50 g KI dissolved in 35 mL water) is treated with saturated HgCl₂ solution until a slight precipitate persists. Then 400 mL of 9 N caustic alkali is added. The solution is diluted to 1000 mL, allowed to settle and decanted. Visual change: brown precipitate. Sensitivity: 1 µg urea. Interference: ammonium salts. These can be eliminated by drying the test solution with a drop of dilute alkali.

5 SELECTED EXAMPLES OF APPLICATIONS OF SPOT TESTS

The classical spot tests have been successfully applied to solving large-scale analytical problems in clinical analysis, in crime laboratories, in judicial chemical studies, in geochemical prospecting, in soil and plant tissue testing, and in air and water QC. Commercial companies are marketing a great variety of compact test systems. Their extreme simplicity, time and money-saving nature and ultimate reliability make these tests very useful. These tests systems, marketed generally by commercial companies in the form of reagent strip systems, prepared reagent pills or tablets constitute a significant proportion of the tools used for solving the total spectrum of analytical problems.

5.1 Applications in Clinical Analysis

Substantial changes in the concentrations of glucose, protein, ketone bodies, bilirubin, urubilinogen nitrites, leucocytes and erythrocytes, and so on in urine may have significant diagnostic value. A simple spot test can give valuable quick information about many health anomalies and provides the possibility of performing many rapid bedside methods for some key materials in the human blood. Selected examples only are presented here.

5.1.1 Tests in Urine

Glucose in urine is screened quickly by enzymatic tests based on the activity of the enzyme glucose oxidase,
which uses dry-reagent chemical technology (Ames Co., Boehringer-Mannheim, Hoechst AG). A firm plastic strip, to which a stiff absorbent cellulose area is affixed, is impregnated with a buffered mixture of glucose oxidase, peroxidase and \( \alpha \)-tolidine. In the first stage of the reaction glucose is oxidized by atmospheric oxygen in the presence of glucose oxidase to gluconic acid and hydrogen peroxide, while in the second stage \( \text{H}_2\text{O}_2 \)/peroxidase oxidizes \( \alpha \)-tolidine to a blue quinoidal compound. The detection is either visual or by simple reflectance instruments, irradiating the dipstick with polychromatic light and measuring the reflected radiation.

**Protein** in urine test is based “on the protein error”. The test exploits the fact that the aqueous solution of the potassium salt of tetrabromophenol-phthalein ethyl ester becomes yellow on addition of dilute acetic acid. If, however, a solution or suspension of native albumin is added to a dilute blue solution, a great deal of acetic acid can be introduced without causing the blue to change to yellow (Ames Co., Boehringer-Mannheim). These standardized tests for the estimation of protein in urine are composed of a strip of absorbent cellulose, one end of which is impregnated with the indicator and buffered at pH 3.

**Ketone** bodies in urine are quickly screened by a dipstick utilizing the reaction of ketones with nitroprusside. The NO group of the nitroprusside gives isonitrosoketone, which remains in the complex anion, with the ketone whereas the \( \text{Fe}^{3+} \) is reduced to \( \text{Fe}^{2+} \) (Ames Co., Boehringer-Mannheim, Hoechst AG). A microprocessor-controlled benchtop reflectance monitor (Kyoto) is designed to measure the change in the color of the strips.

**Bilirubin** in urine can be screened with a tablet-configuration reagent system involving a diazotization procedure, which couples with the bilirubin to give a characteristic purple color. It is a fiber mat test (Ames Co.) using a tablet composed of \( \text{p}-\text{nitrobenzenediazonium p-toluensulfonate}, \text{NH}_4\text{HCO}_3 \), sulfosalicylic acid and boric acid. The sensitivity of the reaction coincides with the lower limit of accepted pathological significance.

**Urobilinogen** in urine is tested by a dip-and-read solid state reagent incorporated in a \( \text{p}-\text{dimethylaminobenzaldehyde} \) and an acid buffer-containing strip. Urobilinogen forms a red Schiff base (Ames Co.).

**Nitrite** in urine tests with the dipstick technique are based on the classical diazotization Griess method (Ames Co., Boehringer-Mannheim, Hoechst AG, Merck Co.). The tests reveal significant bacteriuria when the bacterial count reaches \( 1 \times 10^7 \) per mL of urine.

**Occult blood** in urine is detected on the basis of peroxidase-like activity of hemoglobin, myoglobin and some of their degradation products. The pseudoperoxidase activity of hemoglobin transfers an oxygen atom from the peroxide to the chromogen (\( \alpha \)-tolidine, \( \alpha \)-dianisidine, 2,6-dichlorophenolindophenol). Typical dip-and-read spot tests for occult blood (Ames Co., Boehringer-Mannheim, Helena Laboratories, Finnpipet, Smith Kline Diagnostics) consist of absorbent cellulose impregnated with an organic peroxide, \( \alpha \)-tolidine and buffer system.

**Hemoglobin** in urine is detected with a test strip coated with an organic hydroperoxide. The test strip can be used for the detection of peroxidase-like substances.

**Phenylketones** in urine are detected by a stiff strip of cellulose impregnated with iron(III) and magnesium ions. The desired acidity (pH = 2.3) is provided by the presence of cyclohexylsulfuric acid. The ferric ion forms colored chelates with phenylpyruvic acid, whereas the magnesium ions are masking agents to minimize interference in the color development by urinary phosphate (Ames Co.)

**Chloride** in urine is estimated by discharging the red color of silver dichromate by chloride ion. A solid-reagent spot test for chloride is the Quantab chloride titrator (Ames Co.) It is a chemically inert plastic strip laminated within, which is a capillary column impregnated with \( \text{Ag}_2\text{Cr}_2\text{O}_7 \). The reaction of \( \text{Ag}_2\text{Cr}_2\text{O}_7 \) with chloride produces a white color in the capillary column.

**Ethanol** in urine can be estimated by test strips containing alcohol oxidase and horseradish peroxidase with colorimetric reagents (3-methylbenzothiazolinone hydrazo hydrochrome hydrochloride and 3-dimethylaminobenzoic acid). The urine sample is placed in a centrifuge tube and the test strip is suspended in the air space above the sample. The stoppered tube is heated at 65°C for 5 min and the color development is estimated from a color chart.

**Ascorbic acid** in urine is screened by the reductive decolorization of 2,6-dichlorophenolindophenol. The reagent paper set is prepared by impregnating and drying filter paper in 0.1%, 0.05% and 0.0025% alcoholic reagent solutions. They are suitable for detecting 0.4–1 mg mL\(^{-1}\), 0.2–0.44 mg mL\(^{-1}\) and 0.01–0.24 mg mL\(^{-1}\) ascorbic acid, respectively.

**Cysteine** in urine can be tested semiquantitatively based on the reaction between cysteine, sodium nitroprusside and \( \text{K}_2\text{CO}_3 \) to give a cherry-red complex. Limit of detection: 0.003–0.12 mM cysteine.

**Ionic strength and specific gravity** in urine can be tested using a strip prepared by soaking a filter paper in a solution of sodium heparin and 1 mM methylene blue and attaching the treated sample to a plastic holder. The density of the developed color correlates positively with the specific gravity and ionic strength of the urine sample.

**Edetates** in urine screening is based on the complexing action of edetate anion to remove ferric ion from ferroxamine B immobilized on a Dowex HRC(\( \text{H}^+ \)) resin.
Decomposition of the colored chelate leads to a gradual fading of the deep brown-violet resin beads.

5.1.2 Tests in Blood

Glucose in blood screening is based on the specific glucose-oxidase-peroxidase reaction. In a reaction catalyzed by glucose oxidase, D-glucose is oxidized by atmospheric oxygen to \( \beta \)-D-gluconolactone and \( \mathrm{H}_2\mathrm{O}_2 \). The latter oxidizes the chromogenic system (Ames Co., Boehringer-Mannheim, Biodynamic, Inc.) The test consists of a firm plastic strip to which an impregnated reagent area is affixed. A semipermeable membrane serves as a barrier that retains the high-molecular-weight and cellular components on its surface and can be wiped clean after exactly 60 s. Although significantly hypoglycemic results can be rapidly recognized with the visual test, small deviations from normal values should be confirmed by simple reflectance measurements.

Urea in blood screening is based on the principle of catalyzed hydrolysis of the urea to carbon dioxide and ammonium hydroxide, the concentration of which is measured by the color change of the indicator (Ames Co., Boehringer-Mannheim, E. Merck Co.). The test stick consists of a firm plastic strip to which an impregnated reagent area is affixed. A barrier that retains the high-molecular-weight and cellular components on its surface and can be wiped clean after exactly 60 s. Although significantly hypoglycemic results can be rapidly recognized with the visual test, small deviations from normal values should be confirmed by simple reflectance measurements.

Lactate screening in whole blood is as follows. Apply 20 \( \mu \)L whole blood to a filter paper strip coated on its other side with 3.65 \( \mu \)mol min\(^{-1} \) enzyme activity Pediococcus lactase oxidase, 0.12 \( \mu \)mol 4-amoantipyrine, 0.2 \( \mu \)mol 3-(N-ethyl-N-toluidine)-2-hydroxypropane-1'-sulfonic acid and 18.4 \( \mu \)mol min\(^{-1} \) enzyme activity horseradish peroxidase and attached at one end of a supporting strip. After 1 min the absorbance is measured at 560 nm by a reflectometer.

Cholesterol in blood can be quickly analyzed by use of the cassette strip system, which is based on enzyme action on cholesterol to produce \( \mathrm{H}_2\mathrm{O}_2 \) and determination of the latter (Diagnostics, Inc.). The enzyme is cholesterol oxidase and the strip contains horseradish peroxidase and leuco dye.

5.1.3 Other Tests

Occult blood tests in feces depend on the estimation of peroxidase activity as an indication of hemoglobin content. Reagents used include guaiac, o-tolidine, o-dianisidine and 2,6-dichlorophenolindophenol. The products of Smith Kline Diagnostics and Finnipette are based on the gauaiacum resin, whereas other self-contained systems contain o-tolidine which is oxidized by the peroxidase-like reaction. The reagent tablets (Ames Co. Stoke Pages) contain o-tolidine, strontium peroxide, tartaric acid and calcium acetate. In contact with water, tartaric acid, calcium acetate and strontium peroxide instantly produce \( \mathrm{H}_2\mathrm{O}_2 \), which in the presence of hemoglobin oxidizes o-tolidine to a blue compound.

Spot tests are performed for urinary calculi, the most common varieties of which are the calcium oxalate, uric acid, ammonium urate and magnesium ammoniumphosphate calculi. The test element for oxalate determination contains oxalate oxidase, peroxidase and optional riboflavin (reaction promoter) and quinolines (enhancer). A filter paper is soaked in the first solution containing oxalate oxidase, peroxidase, riboflavin, citrate buffer and sodium alginate and then in the second solution containing tetramethylbenzidine (color indicator) and 3-aminoquinoline. Uric acid and urates are identified by the classical murexide test, heating the sample with a number of drops of concentrated \( \mathrm{HNO}_3 \). The resulting red murexide indicates the presence of urates. Phosphates in calculi are detected by heating the sample with concentrated \( \mathrm{HNO}_3 \) and (NH\(_4\))\(_2\) \( \mathrm{MoO}_4 \) to produce yellow ammonium phosphomolybdate.

Urinary lactic acid screening is based on the transformation of the acid to acetaldehyde, which reacts with sodium nitroprusside to produce a blue color. A sample is added to a tablet, which contains 30 mg CaCl\(_2\) and 30 mg Ce\(_2\)SO\(_4\) in a test tube. The test tube is covered with a piece of filter paper that has been impregnated with a 2.5% aqueous sodium nitroprusside solution and a drop of 10% aqueous morpholine solution. Lactic acid is indicated by the appearance of a blue color.

Sweat test for cystic fibrosis (CF) is based on the elevated concentration of chlorides characterizing this genetic disease. An indicator system for CF consists of three filter paper strips impregnated with 0.1 M K\(_2\)CrO\(_4\). The dry strips are soaked in 0.05 N, 0.066 N and 0.1 N AgNO\(_3\) solution, respectively. The indicator system is attached to a suitable part of the body of the child for 15 min. The indicator strip is removed and read. A positive result is signaled by the decoloration of the originally red-brown papers. Zero or one indicator showing a positive reaction means that the sweat chloride ion concentration is \( \leq 35 \) equivalents per liter and the child is considered normal. Children showing chloride concentration of 35–55 equivalents per liter (two of three papers are reacting positively) need to be checked more thoroughly and concentrations of more than 55 equivalents per liter chloride (all three indicators reacting positively) indicate a high probability of CF.

Urine leucocyte reagent strip (Boehringer-Mannheim, Shiojiri) detects leucocytes in urine. The detection is based on the esterase activity of the leucocytes. Upon contact between the reagent matrix and leucocytes in urine, the indoxyl ester substrate is hydrolyzed by the esterase to indoxyl, which then couples with a diazonium salt to produce a purple azo dye.
5.2 Forensic Application of Spot-test Analysis

Inexpensive screening by spot-test analysis has considerable importance, among other disciplines, in modern police laboratories,\(^1\) mainly as quick first orientation. Only selected examples are described here.

5.2.1 Firearm Discharge Residue Tests

These search mainly for the presence of antimony, barium nitrates, nitrates and lead as residues after shooting. The three elements can be identified by direct test on the cloth used to remove the residues. The cotton cloth is dried and a drop of 10% alcoholic solution of triphenylmethylarsinous iodide is added. In the presence of antimony an orange ring develops within 2 min. After repeated drying the red area is spotted with 1:20 HCl. The appearance of red color confirms barium. Nitrate and nitrite detection on the hand is achieved by removing traces turning vivid red confirms barium. Nitrate and nitrite of a blue spot indicates lead. A reddish-brown spot the red area is spotted with 1 : 20 HCl. The appearance of a blue particle develops is inhibited by the presence of morphine in the sample. The reference surface contains antiperoxidase oxidase and antibody against morphine; the color that is produced by the classical Griess reaction for nitrite is identified on the basis of the peroxidase-like activity of the heme group of hemoglobin. Free hydroxy ions liberated by this activity oxidize colorless phenolphthalein with metallic zinc in basic solution. 0.3 mL of blood is mixed with 0.6 mL of urine by the classical violet iron(III)-salicylate chelate formation. 0.3 mL of blood is mixed with 0.6 mL of urine by the classical violet iron(III)-salicylate chelate formation.

Since the color of the blood and the red azo dye produced by the classical Griess reaction for nitrite are similar, nitrite is detected in this case by fluorescence under UV radiation. A Whatman No.1 filter paper is soaked in freshly prepared 5% solution of o-phenylenediamine dihydrochloride and partially dried. This paper is placed over the suspected area of the gunshot on the clothing. The paper is then placed in a Petri dish containing a 25% NH\(_4\) solution. The paper is illuminated with 254 nm radiation. The yellow fluorescence pattern may be photographed as permanent evidence.

5.2.2 Some Quick Field Tests for Drug Detection

As the problem of drug abuse reaches frightening proportions, the use of simple screening tests are gaining considerable importance beside the enormously useful and sophisticated instrumental methods. Only some representative examples are described here.

Morphine can be detected by an internally referenced test strip immunoassay. The test strips comprise two active surfaces, each of which contains co-immobilized glucose oxidase and antibody against morphine; the color that develops is inhibited by the presence of morphine in the sample. The reference surface contains antiperoxidase and it is used to set the assay detection limit. To determine morphine in urine, the test strip is immersed for 1 min in the sample, then for 10 min in a “developer” solution containing morphine-bound peroxidase, glucose and 4-chloro-1-naphthol as a chromogenic substrate for peroxidase.

Barbiturates in blood and urine samples may be screened by thin-layer chromatography (TLC) on Silica Gel G with CHCl\(_3\)–acetone (9:1) or benzene–acetone (17:3) as mobile phase. Visualization is effected by spraying with diphenylcarbazone–HgCl\(_2\) reagent followed by 1% methanolic KOH.

LSD (lysergic acid diethylamide) is identified by its reaction with Ehrlich reagent (also referred to as Van Urk reagent) producing a purple to deep-blue color.

Amphetamines in urine are sensitively (>0.1 \(\mu\)g) detected by a strip prepared using the Simon reagent. A 2% sodium nitroprusside and 5% aqueous Na\(_2\)CO\(_3\) solution is dried for 3 h at 110°C. A strip is cut from the plate to use in the test. Five milliliters of alkaline urine is extracted with 2mL of benzene and a portion of the benzene layer is spotted onto the strip. When exposed to acetaldehyde vapor an intense blue color results.

Marijuana and coca leaf in illicit cigarette samples can be revealed by shaking the suspected material with a chloroform solution of Fast Bordeaux Gp. salts (C.I. Azoic Diazio Component 1) and with 0.5 M NaOH solution. Cannabinoids are indicated by the appearance of red color in the chloroform layer. The test is applicable to urine samples too.

Salicylates in overdoses are commonly detected in urine by the classical violet iron(III)-salicylate chelate formation. 0.3 mL of blood is mixed with 0.6 mL of methanol and centrifuged. The supernatant solution is filtered and 50 \(\mu\)L of 0.5% FeCl\(_3\) solution is added to 0.2 mL of the filtrate. A violet color at the diffuse interface indicates the presence of salicylate.

5.2.3 Chemical Testing for Blood

Chemical testing is needed to provide physical evidence in cases in which direct visual inspection is not a decisive proof. Chemical spot tests can verify the presence or absence of blood stains, when blood spots on a dark background are not visible or a stain may resemble a bloodstain. In most tests the blood is identified on the basis of the peroxidase-like activity of the heme group of hemoglobin. Free hydroxy ions liberated by this activity oxidize colorless phenolphthalein (reduced phenolphthalein with metallic zinc in basic solution). Addition of a drop of 3% H\(_2\)O\(_2\) solution produces a pink color in the presence of blood traces.
5.2.4 Detection of Semen

Rapid identification of semen is necessitated by the high incidence of sex crimes. Semen is generally identified by its high acid phosphatase content, which hydrolyzes aromatic orthophosphoric acid esters; the phenol resulting from the enzyme-catalyzed reaction can be detected with the Folin–Ciocalteu reagent.

The suspected stain is cut and incubated for 30 min at 37°C with two drops of an 0.1% aqueous solution of disodium phenylphosphate and two drops of Folin–Ciocalteu reagent is added. Phenol forms molybdenum blue on reaction with the molybdate incorporated in the reagent.

5.2.5 Detection of Saliva

Saliva occurrence may be related to spittle, or may be detected on objects in contact with the mouth. Two-thirds of the solid content (0.6%) is salivary amylase. This enzyme, also called ptyalin or diastase hydrolyzes starch to sugar or insoluble cross-linked blue starch polymer to soluble blue fragments. A cutting from the suspected saliva stain is placed in a tube with 1 mL distilled water. Some drops of slurry are made by suspending a reagent tablet in 5 mL water which contains the cross-linked starch polymer (Pharmacia Laboratories, Inc.). After 30 min incubation at 37°C the enzyme action is stopped by adding 1 mL of 0.5 M NaOH solution and the mixture is centrifuged. The appearance of a blue color in the supernatant fluid indicates the presence of saliva.

5.3 Selected Geochemical Applications of Spot Tests

The aim of geochemical prospecting is to find new deposits of metals and nonmetals and to detect crude oil and natural gas accumulation. Chemical tests may indicate the extension of existing deposits. Most of the analytical methods used in geochemistry are instrumental, but because a precision of 10% at the 95% confidence level is good enough for geochemical purposes, at least in the initial stages of the project, simple colorimetric screening tests are still applied, which can be carried out in the field by relatively unskilled operators. Very low capital cost is associated with these methods and the operators can be trained in a relatively short time. Many tests applicable to geochemical exploration are described in Feigl and Anger and Jungreis.

In semiquantitative field tests calibrated sampling spoons and plastic standards, which are prepared by adding suitable dyes to a transparent polyester resin, are used. These standards are far more stable than the conventional liquid standards. No time-consuming preparation of a standard series in the field is necessary and the hardened plastic endures rough handling.

5.3.1 Some Examples in Geochemical Screening

Differentiation between calcite and dolomite is based on the different behaviors of the two carbonates towards weak acids. Calcite is attacked by dilute acid at room temperature. Some crystals of the sample material are placed in a depression of a spot plate. One drop of 0.1% alizarin S solution in saturated tartaric acid solution is added. Calcite is indicated by the appearance of a purple-red precipitate. Dolomite does not react.

A test for beryllium in minerals and ores is based on the conversion of all beryllium compounds to the soluble alkali beryllium fluoride, which reacts with ammoniacal quinalizarine solution and forms a blue-violet complex. The test is specific. The sample is fused in a platinum spoon with an excess of KHF₂. The residue is put in some cold water and centrifuged. A drop of the supernatant fluid is treated with a drop of 0.05% quinalizarine solution in 10% NH₃. A few drops of bromine water destroys the violet color of the excess reagent.

A test for chromium in rocks is accomplished by grinding a tiny particle to a fine powder in an agate mortar and mixing with a four-fold excess of 1:1 mixture of K₂CO₃ and Na₂O₂. A red-hot platinum wire is dipped in the mixture to allow bead formation. The cold bead is dissolved in 1:1 H₂SO₄ in the depression of a spot plate and a drop of 1% alcoholic diphenylcarbazide solution is added. A violet color appears even when the rocks contain Cr in concentrations as low as 0.04%.

Lead in ores and minerals is directly estimated even in the most water-insoluble ores with the rhodizionate reaction. In the presence of Ba or Sr the sample must be fumed with H₂SO₄ beforehand. In a depression in a spot plate a drop of pH 2.8 solution and a drop of freshly prepared 0.2% reagent solution is added. A red-violet color appears on the surface of lead-containing ores. Galena, cerussite, anglesite, crocoite and all water-insoluble lead ores give positive results.

Molybdenum in ores is identified extremely sensitively by the specific color reaction with potassium xanthate. A few grains of the ore in a small crucible are digested with concentrated NaOH and acidified with H₃PO₄. Add a few crystals of the reagent. A dark-violet colored compound MoO₃·2[SC(SH)(OC₂H₅)] forms in the presence of Mo.

5.4 Rapid Selected Screening Tests for Soil and Plant Tissues

The simplification of complex soil chemical analyses became necessary to make them performable by minimally trained personnel. The screening of soil quality is required in conjunction with testing of plant sap.

A test of soil aeration shows the oxygen concentration. The soil is sampled with an open-faced sampler and...
a CaCO₃ suspension is added dropwise to its surface. The extent of penetration of the white chalk particles is proportional to the degree of aeration.

A test of soil pH is accomplished with a mixed indicator of bromocresol green, bromocresol purple and bromocresol red (0.05%, 0.1% and 0.02%, respectively) covering a pH range of 4.0–7.5 (Hellige Inc.). Some dried soil grains are dispersed on a white spot plate and some drops of the indicator mixture are added. Purified barite mineral masks the color of the soil.

A test for exchangeable potassium is necessary to decide whether additional potassium fertilizer is needed. A portable soil test laboratory (Hach Co.) estimates K content using powder pillows containing tetraphenylborate, which precipitates the ion. Because heavy-metal ions interfere with the test, a second powder pillow is included that contains the appropriate complex-binding agents.

A rapid test for nitrate is accomplished by adding a noncorrosive stable reagent tablet to the soil extract. The tablet contains sulfanilamide, N-(1-naphthyl)ethylenediaminedihydrochloride, zinc dust, sulfosalicylic acid, boric acid and magnesium stearate. Rapid reduction of nitrate to nitrite is accomplished by formation of the stable complex between zinc and sulfosalicylic acid. The color formed is compared with a standardized color chart.

Some tests of the sap of plant tissue are very useful as guides to the interpretation of the relative amounts of nutrients taken up by the plant.

A screening test for phosphorus in plant tissue sap is based upon production of the complex phosphomolybdic acid with sodium molybdate and the reduction of the heteropolyacid to molybdenum blue with a tin rod.

The plant tissue is sliced with a sharp knife and a filter paper is wetted with a plant juice. A drop of 0.1% NH₄MoO₄ solution in 0.1 N HCl is added, and a tin rod is pressed to the spot for ca. 10 s. If no color appears, the plant is very deficient in phosphorus, a blue color signals that the plant is adequately supplied with phosphorus.

A screening test for potassium in plant tissue is based on indirect testing for potassium deficiency which is feasible through detection of iron in the nodes of corn stalks. It has been shown that the iron concentration is inversely related to the total potassium in the leaf, nodal and internodal tissue. The stalk is cut with a sharp knife and some drops of KSCN are placed on the nodal area followed by a drop of 6N HCl. K deficiency is indicated by the appearance of a red color.

5.5 Selected Examples of Applications of Spot Tests in Air and Water Quality Control

To protect the worker’s well-being the concentrations of air pollutants in industrial areas must not exceed certain admissible levels. The simple estimation of carbon monoxide in ambient air is carried out by sucking the air sample through a glass tube containing a mixture of iodine pentoxide and fuming H₂SO₄. The extent of green coloration is the indication of CO concentration.

Glass-indicating tubes containing solid reagents are produced and marketed by Drägerwerke AG, Bacharach Industrial Instruments Co., Davis Engineering Co., Union Industrial Equipment Corp., Mine Safety Appliances Co., Acme Protection Equipment Corp. and so on. The simple operating procedure for the detecting tubes is as follows: the two sealed ends of the tube are broken and a recommended air volume is drawn through the tube with a calibrated bellows pump. The color change produced in the tube is compared visually against a set of standard colors. The length over which the color change has occurred in the tube is an alternative indication of the amount of airborne contaminant.¹¹

Arsine has a maximum allowable concentration (MAC) of 0.05 ppm. A typical detector tube for it includes a precleansing layer of cupric ions, which precipitate the interfering reducing gases such as H₂S, H₂Se and mercaptans. The indicator layer is auric gold, which oxidizes the arsine to violet-gray metallic gold (Drägerwerke AG(DW); Mine Safety Appliances Co. (MSA); Union Industrial Equipment Corp. (UIE)).

Carbon monoxide detector tubes utilize the selenium dioxide-catalyzed reaction of I₂O₅ by CO in the presence of fuming H₂SO₄. The interfering materials are selectively oxidized by a precleansing layer ((DW), Bacharach Ind. Instruments (BII)), MSA, UIE).

Chlorine is estimated by an indicator tube, in which the chromogen is o-tolidine. It is oxidized by chlorine into a full-quinoidal yellow compound (DW, MSA, UIE).

Hydrocyanic acid is measured in the indicator tube by its complexation with Hg²⁺ ion, and liberation of HCl indicated by methyl red (DW, UIE).

Sulfur dioxide is estimated in the tubes by reaction with free iodine decolorizing the blue iodine–starch complex. The interference of H₂S is screened out with a cupric compound-containing precleansing layer (DW, MSA, UIE).

5.5.1 Water Quality Screening

Since the Safe Drinking Water Act passed by the US Congress in 1974 the Environmental Protection Agency (EPA) proposed a list of materials that present potential hazards when present in drinking water. Recent water
pollution controls rely heavily on advanced instrumental methods, but spot tests based on simple kits for quick and inexpensive water testing still find wide application and are approved by EPA (Hach Co., Merck Co., Gallard-Schlesinger Chem. Manufacturing, Motte Chem. Products Co., Taylor Chem. Co., Hellige Inc., etc.). In the present limited space only a few of them can be mentioned.\(^{(3,12,13)}\)

The chlorine content in drinking water may be estimated by a stable tablet test. It contains equal parts by weight of KI, potassium bitartrate and soluble starch. Although Br\(_2\), I\(_2\), ozone and other oxidants react similarly to chlorine in this test, their presence is unlikely in water. The EPA accepts the use of the visual comparison method using color-step cubes (Hach Co.) or continuous color discs (Hach Co., Hellige Inc., Merck).

Chromium ions are suspected carcinogens. Their semi-quantitative detection is based on their oxidation in alkaline solution to chromate and subsequent reaction of the latter with diphenylcarbazide. On-the-spot estimation kits use comparator blocks (Merck), calibrated continuous color discs and color cubes (Hack Co., Hellige Inc.).

Cyanide ions are estimated by the demasking of the red-violet mercury(II) dimethylaminobenzylidenerhodamine complex. An indicator stick based on this reaction is on the commercial market (MINTEK, Council for Mineral Technology, Randburg, South Africa).

Nitrate nitrogen in drinking water may be measured semi-quantitatively on test strips (Merck). The test is based on diazotization with an aromatic amine of nitrous acid produced in situ in the reaction zone by a reducing agent and coupled with N(1-naphthyl) ethylenediamine.

Organophosphorus compounds are detected by a field test in water based on an enzyme reaction, namely on the inhibition of cholinesterase activity. Soman (GD) (0.12 µg L\(^{-1}\)), sarin (GB) (9.9 µg L\(^{-1}\)) and tabun (GA) (26 µg L\(^{-1}\)) are detected, whereas the detection limit of the pesticide dichlorvos is 50 µg L\(^{-1}\).

Total hardness of water is evaluated by test strips based on the complexing reaction between the Ca\(^{2+}\) and Mg\(^{2+}\) and ethylenediaminetetraacetic acid (EDTA) disodium salt. The test strip has four zones of gradually increasing reagent content. It is dipped into the water sample and the water hardness is given by the number of zones changing color from green to red-violet (E. Merck, Macherey-Nagel, Ames Co.).

5.6 Food Quality Control Analysis by Spot Test\(^{(3,14)}\)

The partial substitution of one product for another in which the substituted material is inferior to the original product is defined as adulteration. Mineral oil is sometimes substituted for vegetable oil and saccharin is sometimes used instead of sugar. Starch is sometimes used to extend powdered cocoa, and butter can be replaced by margarine.

One of the most common food adulterants is water. Some of the proven toxic materials can be detected by simple screening tests, although most of the analytical procedures used are of a complex nature. A few examples of quick tests are described here.

Saccharin in food may be detected by conversion into phenolsulfonphthalein. The aqueous extract of the food is treated with a few drops of H\(_2\)SO\(_4\) and a few grains of phenol and heated for 10 min at 180 °C. After cooling, it is neutralized with solid Na\(_2\)CO\(_3\). The presence of saccharin is indicated by the appearance of a red color.

Artificial sweeteners (saccharin, cyclamate, dulcin and P-4000) can be separated and identified by TLC on silica gel using a solvent system of butanol, ethanol, ammonia and water. Saccharin is detected as a fluorescent spot under shortwave UV radiation. Successive spraying with solutions of 5% bromine in DMF–alcohol (1:1) and 2% N(1-naphthyl)ethylenediamine dihydrochloride in alcohol reveals cyclamate as a bright pink spot, dulcin as a brownish or blue spot and P-4000 as a brown-pink spot.

Objectionable food preservatives such as H\(_2\)O\(_2\), salicylic acid, boric acid, borates, formaldehyde and sulfites may be screened using simple spot tests.

To test for hydrogen peroxide, equal volumes of milk sample and 1% KI solution dissolved in 2% starch paste are mixed. The presence of peroxides is indicated by the appearance of a blue color.

To test for salicylic acid, 50 mL of the sample or a small volume of the aqueous extract is acidified with 5 mL dilute (1:3) HCl solution in a separation funnel and extracted with diethyl ether. After evaporation of the ether, a drop of 0.5% neutral FeCl\(_3\) solution is added. Yellow ferric salicylate indicates the presence of salicylic acid.

Boric acid produces a deep-red compound when evaporated with tincture of curcuma (turmeric), changing yellow diferuloylmethane into the isomeric red-brown rosocyanin. It turns blue to greenish-black under alkaline conditions. The test is specific for boric acid.

Formaldehyde is extracted from food samples with water and after acidifying with phosphoric acid, the slurry is distilled. One milliliter of the distillate is treated with 5 mL of 0.5% chromotropic acid dissolved in 72% H\(_2\)SO\(_4\). The tube is heated for 10 min in a boiling water bath. In the presence of formaldehyde, a bright-violet color appears.

The presence of sulfur dioxide or sulfite as preservatives is allowed in dehydrated fruits and vegetables, but their addition is prohibited to meats. A test strip for rapid identification of sulfite was prepared from a mixture of orange I (C.I. Orange 20), brilliant green (C.I. Basic Green 1), sodium bicarbonate and alumina. The black strip in contact with the moist sample of food will turn
red within 15 s in the presence of ≥5 µg sulfite and green in its absence.

5.6.1 Tests for Mammalian Feces and Urine Residues in Food

Food-processing plants and warehouses are subject to occasional invasion of rats and mice. The detection of rodent-contaminated lots, urine-contaminated grains, and mammalian feces in foods is a crucial task for law enforcement officials.

The spot test for mammalian feces is based on the fact that the alkaline phosphate isoenzyme present in the feces at certain pH splits phosphate radical from phenolphthalein diphosphate to produce the reddish free phenolphthalein. A pH 9.5 borate–carbonate reaction buffer optimizes the response of the enzyme.

Mammalian-urine contamination in food is detected by strips (Warner-Chilcott) in which the lowest part is impregnated with phosphate-buffered urease and the next band contains K₂CO₃. This area is bordered by a plastic barrier. Above the barrier is the indicator area containing bromocresol green.

Adulteration of milk by addition of (NH₄)₂SO₄ increases both the nonfat solid content and the nitrogen content as determined by the Kjeldahl procedure. One milliliter of milk is treated with 0.5 mL each of 2% NaOH and 2% NaOCl and an aqueous 5% phenol solution. The mixture is heated in a boiling water bath for 20 s. A rapidly deepening blue color appears in the presence of (NH₄)₂SO₄.

To test for differentiation of synthetic from natural vinegar, 10 mL of the sample is mixed with 1 mL concentrated H₃PO₄ and 1 mL 3% KMnO₄ solution. After 5 min the KMnO₄ color changes for natural but not for synthetic vinegar. The solution is then mixed with 1 mL saturated oxalic acid, 1 mL 10% H₂SO₄ and 1 mL Schiff’s reagent (0.1% magenta, 1% anhydrous Na₂SO₃ in 0.1 N HCl). After 5 min natural vinegar gives a violet color reaction, but synthetic vinegar does not.

In a titration, the analyte reacts with a reagent added as a solution of known concentration. The standard solution added from a buret is called a titrant. The volume of the titrant required to react completely with the analyte is measured as the volume at the equivalence point. The notions titrimetry and volumetry have the same meaning. Only well-defined stoichiometric reactions are applied. No additional calibration is necessary, i.e. titrimetric methods are primary methods. Indication of the equivalence point can be carried out by visual indicators or instrumental methods.

Acidimetric and alkalimetric titrations can be described by Bronsted’s theory of strong and weak acids and bases. Theoretical titration curves for reactions of strong or weak acids (bases) with strong bases (acids) are demonstrated. Extremely weak electrolytes can be titrated in the presence of precipitating, oxidizing or complexing agents.

Determinations of metal ions are feasible by means of complexometric titrations. The theory of complexometry, including coupled chemical equilibria, can be derived from the fundamentals of complex-formation reactions in aqueous solutions. Applications are important for analyzing individual metal ions, mainly for their standardization, or for determining the hardness of water.

With regard to the instrumental indications of a titration, the potentiometric, amperometric and conductometric principles are outlined. Amperometric titrations of metal ions are performed with one polarizable electrode. The use of two polarizable electrodes (biamperometry) is especially important to determine the water content of organic solvents.

1 ACIDIMETRIC AND ALKALIMETRIC TITRATIONS

1.1 Introduction
Proton transfer reactions are usually extremely fast, although exceptions, such as the deprotonation of CO₂(\text{aq}), are known, and therefore suitable for application in volumetric procedures. In addition, products of definite stoichiometry are formed and a number of chemical indicators and instrumental detectors are available for the end-point detection.

The instrumental devices are usually based on pH measurement, but other techniques, such as conductometric methods, are also in current use. The only limiting condition is the self-dissociation of the medium (water or any other solvent with acid and/or base properties) which may produce an acid (H₃O⁺) or a base form (OH⁻). It restricts the practical range for acidimetric or alkalimetric titration to a pH range between 0 and 14. For this reason, acidimetric or alkalimetric titrations are sometimes performed in nonaqueous solvents, where a different or larger practical range may apply.

Acidimetric and alkalimetric methods are usually based on pH measurements. With chemical indicators, estimates are usually accurate to within about one pH unit and more accurate determinations are better done with electrodes which respond to the hydrogen ion concentration, or preferably the hydrogen ion activity. Several such electrodes are known.

The most popular and widely used sensor is the glass electrode, although it may exhibit some nonideal behavior in solution with high pH values or high ionic strength. A typical glass electrode shows the
ideal pH response in the pH range from about 1 to 12. A constant potential difference for each pH unit, which is practically identical with the theoretical (minimum) slope, is then observed. The following millivolt difference is calculated per pH unit, from Equation (1):

$$ E = E_2 - E_1 = \frac{2.3026RT}{F}(\log[H^+]_2 - \log[H^+]_1) \quad (1) $$

where $R$ is the gas constant (8.3143 J K$^{-1}$ mol$^{-1}$), $T$ is the absolute temperature (K), $F$ is the Faraday constant (96,485.0 C mol$^{-1}$) and $E$ is the potential difference observed between solutions 1 and 2 with hydrogen ion concentrations $[H^+]_1$ and $[H^+]_2$, respectively. The calculated values are as follows:

1.2 The Titration Curve

The results of a titration are best plotted in an appropriate diagram. However, before one can discuss the results of such a plot, a number of conventions must be introduced and defined. In the following discussion, an alkalimetric titration is outlined, but similar results are obtained in an acidimetric titration and the conclusions may be applied to both types of titration.

The following conventions are introduced:

1. In a theoretical treatment it is assumed that the titrant is sodium hydroxide (NaOH). One is dealing with an alkalimetric titration.
2. The concentration of the titrant (NaOH) is large (>1.0 mol L$^{-1}$), so that no significant volume changes occur during the titration.
3. The concentration of the analyte (acid) is symbolized by $C_a$. Its acid form is HB and its base form is B$^-$. It is assumed that the acid is a neutral species (without charge) and that the base form is a univalent anion (Equation 2):

$$ C_a = [HB] + [B^-] = [HB]_{total} + [B]_{total} \quad (2) $$

The quantity $a$ is the degree of neutralization, defined according to Equation (3):

$$ a = \frac{\text{number of moles of added base}}{\text{number of moles of original acid AB}} \quad (3) $$

$a$ is a normalized quantity that replaces the volume (milliliters) in the titration curve.

The quantity $p_s$ is the degree of protonation, defined according to Equation (4):

$$ p_s = \frac{[\text{protonated base}]}{[\text{total base}]} = \frac{[HB]}{C_s} \quad (4) $$

and therefore (Equations 5 and 6):

$$ [HB] = C_s p_s \quad (5) $$

$$ [B^-] = C_s(1 - p_s) \quad (6) $$

One has to consider Equations (7–11), which enable us to calculate the magnitude of the five unknown quantities, $[Na^+]$, $[H^+]$, $[HB]$, $[B^-]$ and $[OH^-]$:

$$ [Na^+] = a_s C_s \quad (7) $$

$$ C_s = [HB] + [B^-] \quad (8) $$

acid dissociation:

$$ K_A = \frac{[H^+][B^-]}{[HB]} \quad (9) $$

self-dissociation of water:

$$ K_w = [H^+][OH^-] = 10^{-14} \quad (10) $$

electroneutrality:

$$ [Na^+] + [H^+] = [OH^-] + [B^-] \quad (11) $$

We now consider three different titrations.

1.3 Titration of a Strong Acid (Hydrochloric Acid) with a Strong Base (Sodium Hydroxide)

We assume $C_s = 0.01$ mol L$^{-1}$. The values of the different quantities are given in Table 1.

</table>
The results of this calculation are shown in Figure 1, where the pH of the solution is plotted against the degree of neutralization. It represents the curve of any titration of a univalent strong acid with a strong base, and the abscissa may be replaced by the corresponding volume of added base.

At the point $a_s = 1.0$, the expression $\text{d}pH/\text{d}a_s$, representing the slope of the titration curve, reaches its maximum value. It is also the end-point of the titration.

It is easily detected by the pronounced pH jump or by any acid−base indicator with a $pK_s$ value between 4 and 10. This means that the choice of the indicator is not critical. The expression $\text{d}pH/\text{d}a_s$ is at a minimum at the beginning and at the end of the titration curve. This indicates that strong acids and strong bases themselves have a pronounced buffer capacity.

acid with a strong base. Only a limited number of pH indicators can be used for the end-point detection. The pK_i must be between 7 and 10 for the choice of indicator.

1.5 Titration of a Weak Base (Ammonia) with a Strong Acid (Hydrochloric Acid)

The results of the titration of NH_3, C = 0.1 mol L^{-1}, with HCl are presented in Figure 3. It can be seen that at the end-point of the titration the slope assumes a maximum value. However, the pH jump is smaller than in the titration curve of a strong acid with a strong base. It is comparable to the pH jump in the titration of a weak acid with a strong base, but it is shifted toward lower pH values.

As can be seen from the titration curve displayed in Figure 4, mixtures of strong and weak acids in aqueous solutions can be titrated in a single sample with a single titrant (a strong base in this example) if the dissociation constants of the acids are different enough to provide for a sufficient pH jump around the equivalence points. The example shown is a mixture of 0.1 mol L^{-1} HCl and 0.1 mol L^{-1} H_3PO_4. The first equivalence point Cl marks the sum of the concentrations of HCl and H_3PO_4, because the first proton of the phosphoric acid (pK_A1 = 2) and the HCl proton are indistinguishable in aqueous systems. The second dissociation of phosphoric acid (pK_A2 = 7), however, marks its own equivalence point C2, in such a way that the titrant volume C2 – Cl indicates the concentration of the phosphoric acid alone. From that result, the concentration of HCl can also be calculated. B1, B2 and B3 are buffer points.

It is even possible to titrate extremely weak acids with a strong base if the acidity of such an acid is enhanced through a chemical reaction. Several acid enforcement techniques are discussed later in this section.

The most common acids and bases may be arranged in the acidity order given in Table 3, according to the behavior in an alkalimetric or acidimetric titration.

1.6 Acid Enforcement Techniques

Extremely weak acids cannot be titrated with bases in pure aqueous solutions. However, through certain chemical reactions, weak acids may be transformed into strong acids, so that they can be titrated. These reactions involve one of the following.

1. Precipitation of the anion of the weak acid. Barium ions precipitate a number of anions and they may be used for this purpose (Equation 12):

$$2HB + Ba^{2+} \rightarrow \{BaB_2\} + 2H^+ \quad (12)$$

The braces denote the solid state of the barium precipitate, for example (Equation 13):

$$2HPO_4^{2-} + 3BaCl_2 \rightarrow \{Ba_3(PO_4)_2\} + 2H^+ + 6Cl^- \quad (13)$$

2. Oxidation of the weak acid to an oxygen-richer acid, e.g. Equation (14):

$$HNO_2 + \text{"O"} \rightarrow HNO_3 \quad (14)$$

or (Equation 15):

$$H_2SO_3 + \text{"O"} \rightarrow H_2SO_4 \quad (15)$$

3. Complexation: examples include the formation of an ester with a polyalcohol (Equation 16):

$$H_2BO_3 + 2C_3H_5(OH)_3 \rightarrow BO_4(C_3H_5OH)_2^- + H_3O^+ + 2H_2O \quad (16)$$

In a similar way it is possible to titrate the ammonium ion (weak acid) with a strong base after the addition of formaldehyde which converts it to...
2 COMPLEXOMETRIC TITRATIONS

2.1 Introduction

Complexometric titration methods are based on the stoichiometric reaction of metal ions in aqueous solutions with a class of suitable water-soluble bidentate or polydentate ligands, called ‘complexones’.

To be of practical use, the reaction of the metal ions and the complexone must be fast, must result in a water-soluble product and should go nearly to completion when equivalent quantities of both substances are present. The first condition is a kinetic requirement, as in all titrations, and the last implies that the stability constant of the metal complex formed is large.

The most practical ligand systems are those involving chelating polyamines and aminopolycarboxylic acids (the Greek chelé means ‘scissors’). Most complexes with nonchelating monodentate ligands do not have sufficiently large stability constants to fulfill the stability requirement, as can be shown in the example of (monodentate) ammonia complexes with Cu²⁺ and the (tetradentate) trisaminotriethylamine complex with the same metal ion.

2.1.1 Copper–Tetrammine Complexes (See Also Table 4)

A series of four relatively unstable monodentate complex species are formed consecutively (Equations 18–22):

\[
\text{Cu}^{2+} + \text{NH}_3 \rightarrow [\text{Cu(NH}_3\text{)}^2]^{2+} \quad \log K_1 = 4.1
\]

\[
[\text{Cu(NH}_3\text{)}^2]^{2+} + \text{NH}_3 \rightarrow [\text{Cu(NH}_3\text{)}_2]^{2+} \quad \log K_2 = 3.5
\]

\[
[\text{Cu(NH}_3\text{)}_2]^{2+} + \text{NH}_3 \rightarrow [\text{Cu(NH}_3\text{)}_3]^{2+} \quad \log K_3 = 2.9
\]

\[
[\text{Cu(NH}_3\text{)}_3]^{2+} + \text{NH}_3 \rightarrow [\text{Cu(NH}_3\text{)}_4]^{2+} \quad \log K_4 = 2.1
\]

\[
\text{Cu}^{2+} + 4\text{NH}_3 \rightarrow [\text{Cu(NH}_3\text{)}_4]^{2+} \quad \log K_{\text{ST}} = 12.6
\]

2.1.2 Copper–Trisaminotriethylamine Complex (See Also Table 4)

The final complex with the tetradentate ligand is formed in a single step, resulting in a much higher stability
Table 4  Stability constants of some polyamine–metal complexes with copper and zinc (log $K_{ST}$). [Taken in part from G. Schwarzenbach, Analyst, 80, 713 (1995)]

constant of the complex and a steeper titration curve, owing to the chelate effect. The higher stability of a chelate complex is the result of an increase in the entropy of the system. One polydentate ligand, on reaction with a hydrated metal ion (e.g. Cu$^{2+}$ binds four water molecules) liberates several water molecules, increasing the number of unbound particles and hence the entropy (Figure 5).

### 2.2 Complexing Agents

Several useful complexing agents with chelating properties, forming water-soluble chelate complexes, are commercially available. The major field of application is the quantitative determination of water hardness.

#### 2.2.1 Nitrilotriacetic Acid (NTA) (Titriplex I) (1)

$M = 191.14$ g mol$^{-1}$, tetradentate, white powder, easily soluble in alkaline solutions.

![Image of NTA](image-url)

#### 2.2.2 Ethylenediaminetetraacetic Acid (Titriplex II) (2)

$M = 292.25$ g mol$^{-1}$, hexadentate, white powder, not easily soluble in water, but soluble in alkaline solutions.

![Image of EDTA](image-url)

#### 2.2.3 Ethylenediaminetetraacetic Acid Disodium Salt Dihydrate (Titriplex III) (3)

$M = 372.24$ g mol$^{-1}$, hexadentate, white powder, easily soluble in water, the aqueous solution is slightly acidic.

![Image of EDTA sodium salt](image-url)
2.2.4 Trans-1,2-Diaminocyclohexane-N,N',N'-tetraacetic Acid Monohydrate (DCYTA) (4)

$M = 364.36 \text{g mol}^{-1}$, hexadentate, white powder, similar to Titriplex II, but with larger $K_{ST}$ values (see Table 5).

Ethylenediaminetetraacetic acid (EDTA) (hexadentate) is the most frequently used complexometric agent. Structure (5) shows the three-dimensional octahedral structure of the chelate with a divalent cation, displaying the six coordination sites in the ligand, completely surrounding the central ion. The coordination sites are the two amino-nitrogen atoms and four oxygen atoms of the carboxylate groups.

2.3 Simultaneous Equilibria Influencing Complexometric Reactions

The formation of complexes may be accompanied by simultaneous parallel reactions in complex aqueous solutions, according to Scheme 1.

Without such side reactions, which are the ideal case, the total amount of ligand and metal ions would be available for the main titration reaction, as characterized by the equilibrium constant $K_{ST}$ (Equation 23):

$$K_{ST} = \frac{[MY]}{[M][Y]}$$

Prerequisite: $c_M = C_M$ and $c_Y = C_Y$. Owing to each of the side reactions, alone or in combination with each other, the available equilibrium concentration of metal ions and/or ligand may be (much) smaller than the total concentrations. A factor $f$ is introduced to correct from the ideal case ($f$ is between 1 and 0) and to give the apparent or conditional stability constant $K'_{ST}$ (Equations 24–26):

$$f_M = \frac{C_M}{c_M}$$

$$f_Y = \frac{C_Y}{c_Y}$$

$$K'_{ST} = \frac{[MY]}{f_M C_M f_Y C_Y}$$

The conditional stability constant $K'_{ST}$ describes the complex stability of the real system (Figure 6), including all side reactions (Equation 27):

$$K'_{ST} = K_{ST} f_M f_Y$$

An example is the titration of Zn$^{2+}$ with EDTAH$_2$Na$_2$ (YH$_2$) in NH$_3$ solution. The overall reaction of the titration is (Equation 28)

$$\text{Zn}^{2+} + \text{YH}_2 \longrightarrow [\text{ZnY}]^2- + 2\text{H}^+$$

The complex reaction is (Equation 29)

$$\text{Zn}^{2+} + \text{Y}^{4-} \longrightarrow [\text{ZnY}]^2- \quad K_{ZnY}$$

Side reactions are as follows:

Scheme 1
2. The use of metallochromic indicators. These are also complexing agents, but have the special property of color changes between the free ligand and the metal complex. In addition, the stability of the indicator complex must be significantly smaller than the stability of the titrant complex with the same metal ion.

At the beginning of the titration, the indicator reacts with the metal ion, forming a colored metal–indicator complex. During the titration, the stronger metal–titrant complex is formed, which causes the indicator complex to liberate its metal ions around the equivalence point, and to change into the free indicator form, also changing the color. At comparable color intensities of the free and complexed forms, the equivalence point is marked by the appearance of the mixed color, when 50% of the indicator has been liberated.

Metallochromic indicators are available for several metal ions. Some selected examples are as follows:

1. Eriochrome Black T (EBT) (6) (for Mg, Pb, Cd, Mn, Zn).

\[
\begin{align*}
\text{EBT} & \quad \text{NaH}_2E \quad \text{OH} \quad \text{O}_2\text{N} \\
& \quad \text{O}_3\text{S} \quad \text{N} \\
\end{align*}
\]

EBT is a trivalent acid, in practice used as the NaH$_2$E form. The indicator reaction is shown in Equation (34):

\[
\text{HEBT}^{2-} + \text{Mg}^{2+} \rightleftharpoons \text{[MgEBT]}^{-} + \text{H}^+ \quad \text{(34)}
\]

EBT is sensitive to oxidation; the aqueous solution is stabilized with ascorbic acid. Fe, which would block the indicator, is masked with hydroxylamine. Commercially available “indicator buffer tablets” are a mixture of an indicator based on EBT and dyes (color change red–gray–green) with a buffer for pH 10.

2. Calgon carboxylic acid (7), for Ca, and also for Cd, Mg, Mn, Zn.

3. Tiron (8) for Fe$^{3+}$.

\[
\begin{align*}
\text{EBT} & \quad \text{NaH}_2E \quad \text{OH} \quad \text{O}_2\text{N} \\
& \quad \text{O}_3\text{S} \quad \text{N} \\
\end{align*}
\]

\[
\begin{align*}
\text{EBT} & \quad \text{NaH}_2E \quad \text{OH} \quad \text{O}_2\text{N} \\
& \quad \text{O}_3\text{S} \quad \text{N} \\
\end{align*}
\]
2.5 Applications of Complexometric Titrations

As a general rule, high selectivity for the metal ion to be determined by complexometric titrations of metal ion mixtures is required, and can be achieved by exploiting the principles of complex chemistry. The following variables have to be optimized for each individual case:

- selection of ligand
- selection of indicator
- adjustment of pH
- masking of interfering cations, forming stronger chelates with the titrant
- precipitation of interfering cations.

2.5.1 Titration Methods

2.5.1.1 Direct Titration

EDTA forms chelate complexes with many cations, but with different stability. Fe$^{3+}$ and Ca$^{2+}$ can be titrated with EDTA in the same solution, Fe$^{3+}$ at pH 3, and then Ca$^{2+}$ after changing the pH to 10.

2.5.1.2 Back Titration

For metal ions without an appropriate indicator, the sample solution is mixed with a known amount of EDTA in excess, and the excess is determined with Mg$^{2+}$ and EBT.

2.5.1.3 Substitution Titration

The sample solution (e.g. containing Fe$^{3+}$) is mixed with an excess of [MgEDTA]$^{2-}$, then the freed Mg$^{2+}$ can be determined in the usual way.

2.5.1.4 Indirect Titration

The determination of anions is possible by this technique, e.g. sulfate determination: precipitation of the sulfate with excess Ba$^{2+}$, followed by titration of the excess Ba$^{2+}$ with EDTA.

2.5.2 Examples

2.5.2.1 Determination of Water Hardness

Water hardness is represented by the sum of the concentrations of Ca$^{2+}$ and Mg$^{2+}$ in millimoles per liter, and is determined by the simultaneous titration of the two ions with EDTA (Titriplex III) and EBT at pH 10. Masking agents for the major interferents Fe$^{3+}$ and Mn$^{2+}$ (hydroxylamine), Al$^{3+}$ (triethanolamine), and Cu$^{2+}$ (cyanide) are described in the literature.

2.5.2.2 Individual Determination of Ca$^{2+}$ and Mg$^{2+}$

The solution is first adjusted to pH 12 with NaOH, and Mg(OH)$_2$ is then precipitated. Then Ca$^{2+}$ is titrated alone with EDTA and Calgon carboxylic acid. To prevent errors due to coprecipitation of Ca$^{2+}$, the precipitate is redissolved in HCl and Mg(OH)$_2$ and precipitated a second time with NaOH. The exact Mg$^{2+}$ content is calculated from the difference between the total hardness and the Ca$^{2+}$ concentration.

3 ELECTROCHEMICAL TITRATIONS

Electrochemical titrations are classical titrimetric methods with electrochemical end-point detection. They are mainly potentiometric, amperometric and conductometric techniques, as described below.

3.1 Potentiometric Titrations

Potentiometric methods can be used to monitor the course of titration procedures, i.e. to determine the titration end-point if an indicator electrode is available for at least one of the chemical species taking part in the stoichiometric equivalence point of the chemical reactions (either the titrant or the titrand or both). The inflection point of the titration reaction [i.e. with the largest $\Delta E = \Delta V_R$ value ($\Delta E =$ potential difference, $V_R =$ reagent volume)] coincides with the end-point of the reaction if the titration curve is symmetric. In any reaction where the stoichiometry is not 1:1, the titration curve is not symmetric. The titration error associated with the asymmetric titration curves can be partly overcome if the titrant concentration is determined under exactly the same experimental conditions as that of the analyte.

Typical titration curves recorded during the course of a precipitation titration are shown in Figure 7(a–c), together with different end-point determination approaches (direct reading, first-derivative and second-derivative). It must be kept in mind that the error of potentiometric titrations is also affected by the error of the titration end-point location.

The potentiometric method of end-point location can also be used in different automated titrations. However, in any titration procedure, a potentiometric indicator electrode serves only as an end-point indicator, and the analytical concentration of the analyte is determined on the basis of the stoichiometric chemical reaction.

3.2 Amperometric Titrations

Amperometry as a detection mode is widely used in different flow analytical techniques, including flow injection analysis and chromatographic separation methods, and also in conventional volumetric and coulometric titrations. In the latter, current measurement is used to locate the titration end-point.

The working electrode material is more critical in continuous-flow analytical techniques than in titrations,
mainly because of mechanical and long-term operational stability. Different carbon electrodes, such as glassy carbon or carbon paste (a mixture of graphite powder and paraffin or silicone oil), are especially popular for high-performance chromatography and flow injection analysis. For conventional titrations, the indicator electrode is a polarizable electrode, e.g. a dropping mercury electrode (DME) or a platinum or a graphite microelectrode. The other electrode is either a reference electrode (i.e. a nonpolarizable electrode, for which the potential remains unchanged at relatively small current flow) such as a saturated calomel electrode (SCE), or another polarizable electrode. Thus, amperometric titration methods may be subdivided into

- titrations with one polarizable electrode
- titrations with two polarizable electrodes (biamperometric titrations).

### 3.2.1 Amperometric Titration with One Polarizable Electrode

This method involves measurement of the current during the titration in the presence of background electrolyte at a preselected working electrode potential in a stirred solution. The working electrode potential is selected so that the current is due to the electrochemical oxidation or reduction of the analyte or the titrant or both. The amperometric titration curve is constructed on the basis of the alteration of the limiting current versus titrant volume or titration percentage. The shape and characteristics of the titration curves depend on the current–voltage curve for the working electrode and the reversibility of the redox couples involved in the titration reaction.

As an example let us consider the titration reaction in Equation (35):

\[
Pb^{2+} + Cr_2O_7^{2-} \rightarrow PbCr_2O_7
\]

The working electrode is a DME and the reference electrode is a SCE. The working electrode potential is set and kept at a constant value with respect to the reference electrode, so that the limiting current of the reducible species, Pb^{2+}, is measured as a function of volume of titrant added. If the potential is set to 0 V the current remains at zero level up to the end-point because Pb^{2+} is not reduced at that potential. After the equivalence point, the diffusion current rises, owing to the added excess of the reducible chromate ions. The titration end-point is the intersection point obtained by extrapolation of the two linear portions of the titration curve. The titration points close to the end-point are not considered, owing to the dissociation of complexes and the solubility of the precipitates formed during the titration process.

When both titrant and analyte ions give diffusion current at the selected operating voltage, a V-type titration curve is obtained. This is true for the lead–chromate couple if the potential is set to −1 V.

The rotating Pt electrode can also be used as a working electrode in amperometric titrations. The increased limiting current value due to convective diffusion and the lowered residual current at an electrode of constant surface area in the amperometric operating mode significantly lower the detection limit of the technique. Hence amperometric titration can be used for quantitative analyses in the concentration range \(10^{-5} - 10^{-6}\) mol L\(^{-1}\). However, it must be kept in mind that the low overvoltage of hydrogen on the platinum electrode may be a serious problem when using the electrode as cathode in acidic solutions.
The relative error of amperometric titration is less than ±2–3% relative standard deviation. The selectivity of the direct amperometric technique can be improved by appropriate selection of the titration reaction. Thus, compounds of similar \( E_{1/2} \) may be determined in the presence of each other by amperometric titration with the proper selection of the titrants.

### 3.2.2 Amperometric Titration with Two Polarizable Electrodes

Amperometric titrations using two identical polarizable electrodes of equal size are also called biamperometric titrations. The current is measured while a relatively small, fixed potential (10–100 mV) is applied across the electrodes as a function of the titrant volume. One electrode functions as the anode and the other as the cathode. The shape of the titration curve is strongly dependent on the reversibility of the electrode reaction of the titrant and the analyte system. Biamperometric titrations are primarily used for the end-point detection of redox titrations.

Let us consider, as an example, the titration of I\(_2\) with \( S_2O_3^{2-} \) at a low potential, \( \Delta E \), applied across the two platinum electrodes. The titration reaction is given by Equation (36):

\[
I_2 + 2S_2O_3^{2-} \rightleftharpoons 2I^- + S_4O_6^{2-} \tag{36}
\]

For the qualitative interpretation of the titration curves, the \( I_2 || I^- \) and \( S_2O_3^{2-} || S_4O_6^{2-} \) redox couples must be considered. As is known, current will flow in the electrochemical cell if an electrode reaction proceeds at both electrodes. If the fixed potential applied is low, the current flows in the cell when both components of the reversible redox system are present in the solution. The magnitude of the current is determined by the component present in the solution at a lower concentration.

The \( I_2 || I^- \) system is reversible at platinum electrodes, whereas the \( S_2O_3^{2-} || S_4O_6^{2-} \) system is irreversible. Therefore, at a low applied potential, the reaction shown in Equation (37) proceeds:

\[
I_2 + 2e^- \rightarrow 2I^- \tag{37}
\]

and the reaction shown in Equation (38):

\[
S_2O_3^{2-} \rightarrow S_4O_6^{2-} + 2e^- \tag{38}
\]

does not.

Accordingly, at the start of the titration there is no current flow, since no I\(^-\) is present in the solution to be titrated; only the residual current can be measured.

As the titration proceeds, I\(^-\) is generated by the redox reaction and faradaic current flows between the Pt electrodes according to the electrode reactions in Equations (39) and (40):

At the cathode:

\[
I_2 + 2e^- \rightarrow 2I^- \tag{39}
\]

At the anode:

\[
2I^- \rightarrow I_2 + 2e^- \tag{40}
\]

The current is determined by the concentration of the species of the redox couple present in the solution at lower concentration. Hence, the current has a maximum at 50% titration when the concentrations of both I\(_2\) and I\(^-\) are equal, then it decreases owing to the consumption of the I\(_2\) in the titration reaction. At 100% titration and beyond this point there is no I\(_2\) present and only residual current is observed. The titration curves of this type of biamperometric titration are said to have ‘dead stop’ end-points since the current falls essentially to zero at the end-point and remains there.

Similar titration curves can be derived by considering the current–voltage curves of the titrant and the analyte systems and the potential applied.

### 3.2.3 Karl Fischer Titration of Water

The technique can be used for the determination of water in purified solvents and for water of crystallization in crystals. The Karl Fischer reagent, containing, for example, iodine, sulfur dioxide and pyridine in a 1:3:10 mole ratio in methanol, can be used for the direct titration of water in any solvent which does not react with sulfur dioxide and/or iodine. It must be kept in mind that solvents containing aldehydes and ketones cannot be titrated, since they bind sulfur dioxide.

The basis of the method is that sulfur dioxide reacts with iodine in the presence of water, according to the reaction in Equation (41), leading to equilibrium:

\[
SO_2 + I_2 + 2H_2O \rightleftharpoons SO_4^{2-} + 2I^- + 4H^+ \tag{41}
\]

The equilibrium can be shifted to the right-hand side owing to the presence of pyridine (Equations 42 and 43):

\[
\begin{align*}
\text{SN}I_2 & + \text{NSO}_2^- + \text{N} & + \text{H}_2\text{O} & \rightarrow \text{NH}^+ \text{CH}_3\text{COOSO}_3^- \\
2\text{N'}\text{SO}_3^- & + \text{CH}_3\text{OH} & \rightarrow \text{NH}^+ \text{CH}_3\text{COOSO}_3^- 
\end{align*}
\]

The water equivalent of the Karl Fischer standard is determined with a methanol solution containing a known amount of water, e.g. CH\(_3\)COOH : 3H\(_2\)O.
In the course of the titration, the variation of the current as a function of a known volume of standardized Karl Fischer reagent, i.e. \( I - V_{\text{Reagent}} \) (mL) is recorded. The titration end-point is determined by dead-stop end-point detection.

### 3.3 Conductometric Titrations

The specificity of conductometry is enhanced by the addition of a selective reagent. This fact is used in conductometric titrations in which the variation of the electrical conductivity of a solution as a function of the reagent addition \( V_R \) is monitored. The quantitative determination is based on the determination of the reagent consumption until chemical equivalence is reached. The titration end-point is obtained by the intersection of two straight lines fitted to the linear parts of the titration curves (i.e. conductance–titration volume data pairs) recorded during the course of titration.

The main advantages of conductance measurements over classical and potentiometric end-point detection are as follows:

- they can be used for the titration of colored or turbid solutions;
- the titration curve can be constructed on the basis of a few data points, far from the chemical equivalence point.

The latter allows one to overcome problems such as the slow potential response in the neighborhood of the chemical equivalence point in potentiometric titrations. Thus the speed of titrations can be significantly enhanced.

Conductivity end-point detection is used especially in acid–base and precipitation titrations. As an illustration, let us consider the acid–base titration in Equation (44):

\[
\text{H}^+ + \text{A}^- + \text{M}^+ + \text{OH}^- = \text{H}_2\text{O} + \text{M}^+ + \text{A}^- \tag{44}
\]

The underlined ions are present in the solution before the titration end-point.

Thus, with the addition of titrant (MOH), \( \text{H}^+ \) ions are replaced by metal ions \( \text{M}^+ \), while the anion concentration is unchanged. Until the chemical equivalence point is reached, the number of ionic species is unchanged; only the hydrogen ions are exchanged for metal ions, and since the mobility of the hydrogen ions is much greater than that of metal cations, the conductance of the solutions decreases until the equivalence point is reached. After the equivalence point, the conductance corresponds to the excess of hydroxyl ions added, compared with that corresponding to the equivalence point. Thus the conductance increases after the equivalence point as the base concentration increases, and the corresponding titration curve (strong acid with strong base) is V-shaped.

In contrast, in the titration of a weak acid with a weak base, the conductivity of the starting solution is low, owing to limited dissociation. The salt produced in the course of the titration dissociates completely, resulting in a higher conductivity. However, after the equivalence point is reached, the concentration of the strong electrolyte remains constant, and only that of the weak base increases.

In general, a well-defined titration point is obtained only if a strong acid is titrated with strong base or a weak acid with weak base.

Hydrolysis, dissociation of the reaction product or solubility phenomena give rise to curvature of the titration curve in the vicinity of the end-point. At a distance away from the end-point, i.e. from 0 to 50% and between 150 and 200% of the equivalent volume of titrant, these effects are suppressed. By extrapolating these linear portions, the position of the end-point can be determined precisely.

As in all titration techniques, the titrant must be 10 times more concentrated than the solution being titrated, in order to keep the volume change small. If necessary, a correction may be applied; all conductance reagents are multiplied by the terms \( (V + v)/V \), where \( V \) is the initial solution volume and \( v \) is the titrant volume added.

This article describes the concepts of traceability for chemical measurements (in chemical analysis) as they are defined at present, and their relation to analytical chemistry. Traceability concerns the direct or indirect linkage of analytical results to the international metric system of units [Système International (SI)], thereby showing a way to achieving comparability in chemical analysis. The metrological concepts to do this, as they have been developed up to the present, are critically evaluated. They concern the units in which analytical results should be expressed and the tools, such as primary reference methods and primary standards, certified reference materials (CRMs) and other reference materials (RMs), that can be used to increase the accuracy of results of analysis.

1 INTRODUCTION

In the global world of today, the validity of data, including those obtained by chemical analysis, must be properly guaranteed for their quality. There is, at present, growing pressure on improving the overall quality of analytical information and on making it consistent with general metrological principles. There is a widespread belief that, all too often, analytical results are far from being accurate and that these inaccuracies do not occur only on the discipline’s borderline (in the application of methods under development), but also during the application of well established methods. Any methods that might help in increasing the quality of analysis are, hence, welcome. One of the principles selected towards proper quality control is the concept of traceability. The term traceability was gradually introduced into chemical analysis over the last 20 years.\(^1\)

Metrology, the science of measurements, was traditionally used in connection with the measurement of a number of physical parameters (such as length, time, voltage, . . .). Needs have been expressed during the last decade for connecting analytical measurements with the SI and for judging the quality of analytical measurements by the estimation of their uncertainties according to internationally agreed guidelines.\(^2\) For instance, the criteria for the operation of testing laboratories of the EU (European Union) (EN 45001) specify that:

- measurement equipment is regularly recalibrated;
- a RM, traceable to a national or international standard reference material (SRM), is used whenever possible;
- whenever traceability to national/international standards of measurement is not applicable, the laboratories shall provide evidence of accuracy by indirect means, e.g. by participating in programs of interlaboratory comparison.

These guidelines impose concepts connected with traceability as one of the requirements of the results of chemical analysis. In general terms, traceability refers to the direct link between the producer of analytical data and the national and international measurement system.

In the vocabulary of the International Organization for Standardization (ISO) (Geneva, Switzerland), for quality management and quality assurance, traceability is rather broadly defined as “the ability to trace the history, application or location of an entity by means of recorded identifications” (ISO 8402, 1994). For calibration purposes there was added to this definition, “traceability relates measuring equipment to national or international standards, basic physical constants or RMs”. In connection with chemical measurements, the basic concepts of traceability were more specifically defined by the CCQM (Consultative Committee on Quality of Measurements) as “the property of the result of a measurement whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties”. In this definition, the uncertainty of a measurement is the parameter associated with the result of a measurement, that characterizes the dispersion of the values that could reasonably be attributed to the measurement.\(^3\) According to common metrological concepts, all this should be achieved by
the application of a so-called metrological pyramid with primary standards on the top and using international and national metrological laboratories as the privileged intermediates to the SI system. Basically, the application of these principles should guarantee that the analytical results are accurate (true) and comparable both over time and between individual laboratories. Implied also is that the results are given to the user with sufficient information on their significance expressed as confidence levels or uncertainties.

The basic definition of traceability given by the CCQM was implemented in recent years, mostly in connection with the question of how this unbroken chain of comparisons with the SI system could be achieved in analytical practice. The sometimes very rigid aspects that have been put forward for doing this are not always well accepted in the analytical chemistry community.\(^{4–7}\)

Most of the differences that arise are connected with the differences between analytical chemistry on one side and metrology on the other, as distinct scientific disciplines (see further).

It is of interest to determine to what extent the concepts of traceability are applicable in analytical practice and how they might be put to use for increasing the overall quality of analytical results. As a concept, traceability is then reduced to an important and practical tool instead of a dogmatic undertaking. It can be useful to complement or assist any other available tools for achieving high quality and comparability of analytical data.

2 ANALYTICAL CHEMISTRY AND CHEMICAL ANALYSIS

In its diversity of approaches, analytical chemistry is a complex science that relies on a variety of different techniques and concepts. Chemical analysis is also an important factor in the economy and society as they exist today. Chemical analysis involves a considerable economic cost, but it results in considerable added value of the goods produced and helps in promoting international trade. Chemical analysis constitutes a considerable fraction (up to 6%) of the gross national product that advanced nations spend on measurements and related operations. It is important for advanced society in, for example, environmental protection, food, safety and health. It is, hence, essential that results are trustworthy and reliable for the many diverse purposes they serve.

Over the last 50 years, the advent of a number of rapid, highly sensitive and precise instrumental analytical techniques has contributed to a tremendous increase in the overall number of chemical (analytical) measurements. These instrumental techniques now cover nearly every imaginable analytical need. Most of these techniques are comparative in nature (requiring calibration of the analytical signal) and suffer from a number of matrix-dependent influences in the expression of the relation between the signal measured and the concentration of the measurand (the selected item to be quantified in a sample, the analyte). They therefore need careful calibration and the validation of the methods and procedures through the use of RMs, thus linking the measurements to the truth and achieving traceability in its broadest definition.

Chemical analysis is a particular measurement process, distinct from the physical measurement processes. The differences in attitude between analytical chemists and metrologists are conceptual and terminological. They are the result of the push to solve the problems that analysts face through the exploitation of the analytical sciences, as opposed to the dogmatism behind the metrological efforts for achieving utmost accuracy, sometimes at any cost that this might imply.

The analytical act is an indivisible process including the measurement equipment, the measurand in its relation to the particular environment (the sample subjected to analysis), and the very often complex overall procedure that leads to the result. The errors of the determination depend on random error sources in sampling, sample preparation for analysis during transfer, preparation and storage and chemical separations. The quality of the results depends also on systematic sources of error such as incomplete recovery and other losses of the measurand, interferences and contaminations. Analysis based exclusively on a measurement is extremely rare in practice (limited to some methods of nondestructive instrumental analysis).

In its application, analytical chemistry is complex as it draws on any available technique or information that is suitable for the specific purpose involved, namely deriving the concentration of the measurand in a given object subjected to analysis. In its applications, analysis is also very strongly dependent on the properties and the overall composition of the samples involved. Analytical procedures and the use of measurement standards are very often different when applied to different types of samples. Therefore, processes of method validation need to be related to the overall analytical act and to the specific sample involved in order to cover errors due to sampling, incomplete recovery of the analytes, contaminants, reagent blanks and interferences. This is commonly achieved by studies of all parameters affecting the analysis in interlaboratory comparisons, the use of reference samples, proficiency testing and other practical and operational validation tools.

Owing to the importance of matrix effects, the appropriate standards for calibration and reference
to the measurement system are, in general, lacking. Measurement standards for most physical measurements, on the other hand, are, in general, readily available. There is a widespread and growing need for more (and more reliable) reference samples. At the same time, it is realized that well-characterized RMs are extremely costly to produce, store and distribute.

3 TRACEABILITY AND ANALYTICAL CHEMISTRY

It is important to review the basic concepts behind traceability as they have been implemented in practice by the CCQM. This consultative Committee of the International Committee for Weights and Measures (CIPM) was established in 1993 to translate the traceability concepts to chemical analysis. The major items addressed by the CCQM up to now are as follows:

- International comparability of chemical measurements is to be achieved by linking all measurements (analyses) to the SI system and expressed as the basic SI unit of amount of substance with the mole or derived entities as the unit. Since its introduction in 1971, the mole is the amount of substance containing as many elementary items (atoms, ions, ...) as there are atoms in 0.012 kg of carbon-12. Analytical chemistry, on the other hand, is used to express results of the measurement process in concentration units expressed in different units according to the specific problem being addressed. As long as these concentration units are properly defined (and traceable to the SI basic unit), there cannot be a problem in converting results. There is an extensive literature on the formal aspects of the measurement unit, e.g. on the way to express it (with the subtle difference between mass and amount of substance and other problems of nomenclature), how it relates to the different elements (e.g. for polyisotopic elements such as lead with a variable isotopic composition) and to the Avogadro constant and the uncertainty with which it is known at present (ca. 10^{-6}, or more than sufficient for nearly all analytical purposes).

- The CCQM defined the analytical methods for measurement of the amount of substance in mole units that are directly linked to SI units as so-called primary methods. The term definite method was used earlier. The definition of primary methods implies that these methods are completely described and understood and that a complete uncertainty statement can be expressed in terms of the SI units without reference to a standard of the quantity being measured. The basis of the choice of methods is that they are specific for the measurand and that all parameters or corrections dependent on the matrix or other constituents are known or can be calculated with appropriate uncertainty. The requirement that no comparative measurements are allowed with the pure or diluted entity subjected to analysis, excludes nearly all of the available instrumental analytical techniques.

3.1 Primary Methods

Only a very limited number of methods have been identified as having the potential to be a primary method. Methods selected so far are as follows:

1. Isotope dilution mass spectrometry (IDMS), a method whose result depends on the accurate mass spectrometric determination of isotope ratios of unknown sample, a spiked sample brought in full equilibrium with the spike. It should be taken into account that for elemental analysis the method is only applicable to part of the periodic system (the polyisotopic elements), and that it is slow and expensive when used with thermal ionization mass spectrometry. It might become more easily applicable for elemental analysis with inductively coupled plasma mass spectrometry. Its use can be extended, however, to the determination of an extensive list of organic compounds through the use of labeled compounds, e.g. through the addition to the sample of a 13C-enriched homolog of the measurand.

2. Coulometry and differential scanning coulometry, where the analytical signal is directly related to the measure and through the Faraday constant.

3. Reaction chemistry using gravimetry and titrimetry. These methods are based on stoichiometric solution chemistry. Gravimetry derives the result from the measurement of the mass of a slightly soluble product, and thus relates directly to the measurement of mass. Volumetric analysis is based on the measurement of the volume of a primary standard solution of another chemical entity, with pure Ag as the ultimate standard.

4. Determinations based on lowering of the freezing point, change of the freezing point and other methods based on the theorem that in sufficiently dilute solutions the solvent behaves ideally.

Primary methods are carefully defined by the CCQM as methods for the determination of the amount of substance in pure or simple compound systems, i.e. in samples which do not contain any impurities which might potentially act as interferences (and, hence, become an
error source) in the primary method applied. The CCQM considers it as one of its future tasks to investigate the applicability and robustness of these methods for complex mixtures encountered in practical analytical chemistry. Many reports, however, tend to identify primary methods already as methods of analysis (to be used on complex samples of unknown overall composition). This is, of course, an overoptimistic (and unwarranted) enlargement of the definition that would, for example, imply that all titrimetric methods of analysis could be considered as primary methods, putting aside any of the many potential interferences that occur in their application in complex samples. Koltzoff’s handbooks on titrimetry are full of such interferences!

The CCQM is at present evaluating other analytical methods for their potential of being promoted as primary methods, e.g. nuclear magnetic resonance (NMR) spectrometry. It also recently (1998) redefined and extended the definition of “primary methods”. A distinction was made between a primary “direct” method (e.g. coulometry, gravimetry) that can be used to measure the value of an unknown without reference to a standard of the same quantity, and primary “ratio” methods where the value of the unknown is determined by means of the measurement of a ratio of the unknown to a standard of the same quantity (e.g. IDMS). The latter primary methods thus rely on reference of the unknown to a reference that is itself traceable to SI units. The distinction was made because three of the methods originally identified by the CCQM as “primary” are primary ratio methods, e.g. IDMS, which relies on a gravimetric assay (or an assay with another primary direct method) of the pure spike.

### 3.2 Primary References

According to the definition, these methods, and no others, can be used for the determination of the purity of materials used in the preparation of (primary) RMs. A primary reference material (PRM) is one made on the basis of primary methods, thus primary standards and primary methods are linked to each other, the latter being always the result of measurements with the first. PRMs can be used for calibration of instruments and, hence, are of help in the measurement step of the analytical procedures to evaluate uncertainties in the measurement process and, for example, to evaluate the extent of matrix-dependent effects.

Considering the limitations in available primary methods, emphasis must be placed on other measurement standards. For determinations of nonisolated substances, (those present in complex matrices) it is considered that other RMs are needed which are firmly linked to SI units by using primary methods. In practice, this implies that such RMs must be artificially produced, e.g. by mixing them together starting from the PRMs. This distinguishes them from any real-life RMs (matrix RMs; see further).

The possible set of ways of realizing traceability to SI units using intermediate points and primary methods is shown in Figure 1. In Figure 2, the structure is schematically shown of how a network of laboratories, ranging from international metrology institutes, over secondary (national) reference laboratories, could link working-level laboratories to the SI units.

In the physical measurements field, networks linking working-level laboratories to internationally recognized metrology institutes exist, but not at present in chemical analysis.

3.3 Standard or Reference Materials

The term standard material or RM is used to describe a generic class of stable and well characterized materials with one or more properties or components experimentally determined within stated measurement uncertainties. There is an extensive terminology, even a hierarchy on the basis of traceability, on such less stringently defined RMs. As opposed to a PRM, as defined in the previous section, a secondary or composite RM is a standard whose value is assigned by comparison with a primary reference of the same quantity. Their certification requirements are less stringent than those of the primary references. They can be used for calibration and validation of analytical methods or measuring systems. Composite RMs can be made up artificially from synthetic RMs derived from pure materials or using PRMs. Such synthetic RMs, however, are usually not appropriate for most of the analytical problems in day-to-day practice.

A traceable CRM relying on primary methods is available only in exceptional circumstances, as the exclusive use of primary methods of analysis is impossible in practice. For trace element determinations, the National Institute of Standards and Technology (NIST) employs, whenever possible, methods such as IDMS for its CRMs (NIST SRMs).

CRMs, accompanied by a certificate, are materials in which one or more components are certified by procedures which establish their traceability and whose certified values are accompanied by a stated level of confidence. The stability and homogeneity of such materials must be carefully assessed. They constitute the simplest and most appropriate way for a laboratory to ensure traceability and to verify the analytical procedure. It is important that these CRMs are “matrix” CRMs. Matrix CRMs are those of partly known matrix composition, based on natural (nonsynthetic) samples. Using these in analysis for validation purposes, values in disagreement with the certified values provide a warning of errors of which the sources must be identified. Matrix CRMs with a natural composition are preferred in chemical analysis. Their certification can only be done using complex procedures with limited precision compared with those based on primary methods.

The ISO (Guide 35) describes how the production and use of RMs should be carried out as “the certified value should be an accurate estimate of the true value with a reliable estimate of the uncertainty compatible with the end use requirements”. Many existing CRMs, such as those issued by the EU, use a range of analytical methodologies regardless of whether they are directly linked to the SI system or not, provided that they are properly calibrated.

The majority of existing “matrix” CRMs are usually characterized by interlaboratory studies using different analytical techniques. According to the current state-of-the-art in RMs certification, a number of selected participants in a certification deliver a set of replicate measurement results. In the statistical evaluation a consensus value is obtained as the mean of means of the participants’ replicate data, excluding outliers. The uncertainty is given as the standard deviation of the mean or a multiple of this (e.g. providing the 95% confidence interval of the true value).

The strict reliance on the SI system by primary methods for the determination of certified concentrations remains illusory in many cases, except for the occasional use of IDMS. Even this primary method of analysis is not fail-proof in this application for matrix CRMs, as chemical equilibrium between the spike and the measurand often cannot be ensured.

CRMs should be the major bridge between metrology laboratories and the broader community. Most CRMs are issued by organizations other than metrology laboratories and are produced through certification campaigns that rely on a plethora of different analytical methods. Hence strict traceability of the data produced according to the SI system is not always ensured.

Hence, such CRMs are consensus items for which it is assumed that the use of different methods of analysis will cancel out systematic variations if independent reference and validated methods are employed by expert analysts, working independently under carefully prescribed and controlled conditions. A typical certification scheme, as applied by the Community Bureau of Reference (BCR) of the Standards, Measurements and Testing (SMT), Program of the EU is shown in Figure 3. A set of data

belonging to a specific certification exercise is illustrated in Figure 4.\textsuperscript{13}

3.4 Confidence Limits

In addition of accuracy (absence of systematic errors), the implementation of traceability also concerns stated uncertainty (the coefficient of variation or confidence interval) of analytical measurements. The “bottom-up” approach of the ISO consists in the estimation of all the individual error components in a total uncertainty budget and combining the quantified individual uncertainty components.\textsuperscript{14} Another approach (top-to-bottom) is based on the participation of a number of laboratories in method performance exercises.\textsuperscript{15} Both systematic and random errors occurring between laboratories are considered as random errors and are used to estimate statistically the random measurement error. This method has the advantage over the former approach that unforeseen errors turn up in the uncertainty estimates. It is the method of choice for analytical chemists. Metrology advocates the former.

Analytical chemists are accustomed to report their measurement results together with the standard deviations of individual results (the repeatability). It became clear from many interlaboratory comparison studies that discrepancies (the reproducibility) are consistently much larger than these repeatability estimates. Hence it is necessary that more emphasis is placed on the determination of the uncertainty of analytical methods.\textsuperscript{16} Approaches for evaluating total measurement uncertainty may rely on metrology laboratories and on carefully selected analytical laboratories using a standard operating procedure (SOP). CRMs and proficiency tests can be used for this purpose. The total analytical error being larger than the measurement alone, it is necessary that other sources of measurement uncertainty are accounted for, e.g. those resulting from sampling.

Many papers discussing traceability concepts are heavily biased towards analytical determinations that require extremely high accuracy and, hence, full metrological orthodoxy. It is obvious that in specific situations strictly defined concepts must be enforced and adhered to, and even that in some circumstances comparability of measurements is more important than the true analytical result as such. Chemical analysis being a problem-solving tool, its measurement results should provide answers to specific problems in science, society and industry. In defining the measurement process, it is necessary to define the degree of accuracy necessary for “fitness for purpose”. Economic considerations come in here: it is not necessary that the accuracy of the determination is higher than required for the specific problem at hand,

Figure 4 Result of certification of dibutyltin in CRM 477 (organotin compounds in mussel tissue) using results from a number of laboratories. The different methods used are identified by acronyms with hyphenated methods of analysis. (Reproduced by permission from Quevauviller.\textsuperscript{13})
provided that stated uncertainties include the true value and that measurements are comparable. In many discussions on traceability, measurement errors are insignificant compared with both fitness of purpose requirements and other error sources in analysis or sampling.

4 CONCLUSIONS

In the fields of physical measurements (length, voltage, etc.), straightforward calibration procedures ensuring direct traceability to national and international calibration systems are generally applicable. In chemical analysis, calibration and traceability to the SI system is considerably less obvious. The underlying concepts originating from metrology, i.e. measurement science, tend overly to reduce or simplify the analytical practice to the measurement. The measurement step is only one, often minor, part of the entire analytical process, among many other important parts that contribute to the overall bias of the results and to the confidence limits.

Traceability is not an end in itself, but is just one of the possible ways to foster quality assurance as a drive towards analytical reliability. The concepts as put forward by the CCQM are heavily centered on the measurement part of the overall analytical process. Their practical application is hampered by the adoption of a number of strict rules, so that truly traceable CRMs relying on primary methods are only available in rather exceptional circumstances.

Accuracy remains a central theme in analysis and its pursuit can no longer be the work of a single analytical chemist but requires comparative studies involving many methodologies and many, widely dispersed, experts. It is sensible to expect that pooling different kinds of data (methods and users) will lead to better estimates of the truth, even if some of the contributions are more reliable than others. There is a need for education, to increase the awareness of analysts about quality enforcement and control.

The SMT Program of the European Commission (Fourth Framework Program 1994–1998) included measures for the maintenance and development of metrological systems. It put emphasis on both (i) the accuracy and traceability of measurements to the SI system and (ii) the development of metrology in chemistry and routine analysis, including the development, improvement and validation of analytical steps (sampling, digestion, preconcentration, separation and calibration). The Fifth Framework Program (1999–2002) is less specific and avoids any direct reference to traceability. The Program description makes the following general comment on measurements and testing: "...by ensuring that European standards and testing laboratories provide consistent measurements and tests which are equivalent to similar measurements made by Europe’s major trading partners; by making available technical tests, CRMs and measuring instruments for use in Member States in order to assure compliance with Community directives; by supporting standardization and certification...”.

Quality control of the laboratories depends on the availability of CRMs, round-robin studies, intercomparisons and proficiency tests between methods and between laboratories. Of special importance is the full knowledge of the complex analytical process and the painstaking pursuit of the true value by the definition of all sources of errors, and the application of an adequate error source budget. Internal quality control (IQC) comprises all procedures used in a laboratory that enable one to assess the quality of each run of analysis produced and accept the results only if they fulfill a predetermined standard with a high probability. In general, IQC schemes operate by the inclusion of traceable control materials and by the duplication of measurements. The pursuit of accuracy in chemical analysis is a matter of quality assurance, in the laboratory and in the system, less one of the concepts of traceability alone as a means for anchoring measurements in time or space. A number of analytical measurement practices as advocated by international organizations such as the European Collaboration in Measurement Standards (EUROMET), Cooperation on International Traceability in Analytical Chemistry (CITAC), International Union of Pure and Applied Chemistry (IUPAC), ISO and International Measurement Evaluation Program (IMEP) to increase accuracy of analysis are given in Table 1.

Organizations requiring a high throughput of analyses are now undergoing a paradigm shift in which performance is specified, not the specific methodologies used. The United States Environmental Protection Agency (USEPA), for example, is at present shifting to a “performance-based measurement system” (PBMS) for the environmental analyses of hazardous wastes. In this system, performance needs (instead of specific measurement technologies) are specified for reliable, cost-effective analyses, thus avoiding costly measurement overkill. Feedback on successes and failures are then used to expand knowledge on new or modified approaches.

---

Table 1 Valid analytical measurement practices
(Reproduced by permission from King

- Work on agreed customer requirements
- Use validated methods/equipment and qualified staff
- Participate in independent assessment of technical performance (proficiency testing)
- Ensure comparability with measurements in other laboratories (traceability and measurement uncertainty)
- Use well-defined quantity control and quality assurance practices
in a flexible working environment and in “real-world” conditions. In such types of approaches the generator of the data becomes directly responsible for demonstrating regulatory compliance by defining a sampling/analysis plan and strict record-keeping of proofs of concepts and levels of validation.

Ultrafast Laser Technology and Spectroscopy

Gavin D. Reid
University of Leeds, Leeds, UK
Klaas Wynne
University of Strathclyde, Glasgow, UK

1 Introduction

Ultrafast spectroscopy has become one of the most active areas of physical chemistry. Rather than postulating mechanisms for chemical and biological reactions, ultra-short laser pulses can now be used to observe and even control the outcome of reactions in real time. Because of our improved understanding of reaction pathways, the “arrows” describing purported electronic motion in mechanistic organic chemistry are no longer sufficient. A state-of-the-art laser system can generate 1-J ca. 20-fs pulses and the peak fluence at the focus of these lasers can exceed $10^{20}$ W cm$^{-2}$. In contrast, the total solar flux at the Earth is only $10^{17}$ W. An exciting new era is beginning, which will allow the possibility of using these intense ultrashort laser pulses as sources of short X-ray and electron pulses. These will reveal the positions of atoms as a function of time as reactants proceed to products through the transition states. More routinely, femtosecond lasers can be used to detect and monitor transient chemical species in solution or the gas phase, to image living cells with micrometer resolution, for laser ablation mass spectrometry (MS) and micromachining applications, which will all be of immediate interest to the analytical chemist.

With the invention of flash photolysis in 1950, radical intermediates were observed by light absorption (rather than fluorescence) during the progress of a chemical reaction. When the pulsed laser followed, nanosecond experiments derived from the flash-photolysis technique were to reveal the chemistry of singlet states in solution. However, it was not until the mode-locked ruby and Nd:glass lasers were built in the mid-1960s that the picosecond timescale became accessible and the field of “picosecond phenomena” was born. When excited-state processes were studied in the picosecond domain, such as energy redistribution in molecules and proteins, proton and electron transfer reactions, photoisomerization and dissociation, and relaxation in semiconductors, many
measured rate constants were found to be instrument limited. Nevertheless, important results such as the observation of the “inverted region” in electron transfer reactions\(^\text{5–7}\) and Kramers’ turnover in excited-state reactions in solution.\(^\text{8,9}\)

However, ultrafast spectroscopy was revolutionized in the 1980s by the invention of the colliding-pulse mode-locked (CPM) dye laser, which generated 100-fs pulses in its early form\(^\text{10}\) and 30-fs pulses as the technology was perfected.\(^\text{11}\) This ring laser, operating at about 620 nm, coupled with improvements in dye–amplifier chains,\(^\text{12}\) allowed the exciting field of femtochemistry to be developed,\(^\text{13}\) which will be discussed briefly in section 5.1, and the generation of 6-fs probe pulses,\(^\text{14}\) a record which stood until very recently. Self mode-locking in Ti:sapphire-based lasers was discovered\(^\text{15}\) in 1990 and the early 1990s brought a new revolution – simplicity of use – and, with it, the commercialization of ultrashort pulse technology. Ti:sapphire oscillators now produce 10–20-fs pulses routinely and 4–5-fs pulses in optimized configurations using mirrors designed to reverse the “chirp” introduced by the Ti:sapphire rod. The limiting factor on the exceptional stability of these oscillators is the pump source and here diode-pumped solid-state laser sources are rapidly replacing large, expensive, low-efficiency ion lasers.

In parallel with improvements in oscillator technology, the technique of chirped pulse amplification\(^\text{16}\) using solid-state gain media in regenerative or multi-pass schemes has replaced the dye–amplifier systems of the past. A typical amplifier for routine chemistry applications produces 1 mJ per pulse at a 1-kHz repetition rate or 100 mJ at 10–20 Hz with a duration between 20 and 100 fs. Moreover, a Ti:sapphire laser oscillator and amplifier combination can be purchased in a single box less than 1 m square, operating at mains voltages with no external water-cooling requirements. Total hands-off operation is a reality and, in fact, the complete laser system can be computer controlled.

In the next section, we shall describe the technology behind Ti:sapphire lasers and amplifiers and discuss how light at almost any frequency from X-rays to terahertz can be generated and employed by the chemist. A history of the field can be found in the papers submitted to the biennial conference ‘Ultrafast Phenomena’, the proceedings of which are published in the Springer Series in Chemical Physics, which is now in its eleventh volume.\(^\text{17}\)

### 2 ULTRAFAST LASERS AND AMPLIFIERS

#### 2.1 Oscillators

Ultrashort pulses are generated by mode-locked lasers. By constructive interference, a short pulse is formed when many longitudinal modes are held in phase in a laser resonator. Various techniques have been employed, usually grouped under the terms “active” or “passive” mode locking and descriptions of these can be found in many standard texts\(^\text{18,19}\) and review articles.\(^\text{20}\) Active mode locking uses a modulator in the laser cavity whereas passive schemes use a saturable absorber, often a thin semiconductor film, to lock the relative phases. Modern solid-state mode-locked lasers use a different scheme called self-mode-locking and titanium-doped sapphire (Ti:sapphire) has become by far the most common laser material for the generation of ultrashort pulses. Developed in the mid-1980s,\(^\text{21}\) Ti:sapphire has a gain bandwidth from 700 to 1100 nm peaking around 800 nm, the broadest of the solid-state materials yet discovered, high-gain cross-section and extremely good thermal conductivity. Mode locking is achieved through the action of an instantaneous nonlinear Kerr lens in the laser rod (see section 3.1). The peak fluence of the laser approaches 10\(^{11}\) W cm\(^{-2}\), which is enough to focus the beam as it travels through the gain medium on each pass. This Kerr lens then couples the spatial and temporal modes and maintains phase locking.

A basic oscillator–cavity configuration\(^\text{22}\) is shown schematically in Figure 1. The laser is pumped by about 5 W from a continuous wave (CW) laser source, usually now an intracavity-doubled diode-pumped neodymium laser. This light is focused into the Ti:sapphire rod, collinearly with the laser axis, through the back of one of the mirrors. The cavity consists of a Brewster-angle cut Ti:sapphire rod, 5 mm or less in length, doped to absorb about 90% of the incident pump radiation, two concave focusing mirrors placed around it, a high reflector and an output coupler. A pair of Brewster-cut fused-silica prisms are inserted to control the spectral dispersion (chirp) introduced in the laser rod. Dispersion arises from the variation of the refractive index of the material across the gain bandwidth of the laser, which can lead to a temporal separation of the resonant wavelengths and

![Figure 1](image)

**Figure 1** Diagram of a basic self-mode-locked Ti:sapphire oscillator showing the cavity layout. The pulse is coupled out from the dispersed end of the cavity, which requires a pair of matching extracavity prisms.
place a limit on the generated bandwidth (see section 2.2). The cavity dispersion, coupled to the Kerr lens effect, is an intrinsic part of the pulse-formation process. Ordinarily, the Kerr lens in the rod would contribute to the overall loss but this is overcome by a small adjustment to the resonator. Displacement of one of the curved mirrors by only ca. 0.5 mm pushes the cavity into pulsed mode. Here the cavity is corrected for the nonlinear lens effect and CW operation is restricted. Pulsing is established by perturbing the cavity to introduce a noise spike, literally by tapping a mirror mount. This configuration delivers 12-fs pulses centered at 800 nm with 5 nJ energy at an 80-MHz repetition rate. Using a shorter rod, shorter pulses have been obtained\(^{(23)}\) as the dispersion is better compensated and space–time focusing effects are controlled. The laser repetition rate can be adjusted by the insertion of a cavity dumper in a second fold, without prejudice to the pulse duration.\(^{(24)}\) The use of mirrors that have dispersion opposite to that of the rod\(^{(25)}\) obviates the need for prisms entirely. Alternatively, a mixture of prisms and mirrors can be used to generate pulses as short as 5 fs.\(^{(26)}\) At the time of writing, the use of mirrors with well-defined chirp characteristics is complicated by the demand for extreme tolerances in the manufacturing process. Many schemes have been proposed for self-starting oscillators, perhaps the best of which is the use of a broadband semiconductor saturable-absorber mirror in the cavity.\(^{(27)}\) Advances in these areas will surely continue.

Other important solid-state materials include Cr:LiSAF (chromium-doped lithium–strontium–aluminum fluoride), which can be pumped by red diode lasers and operates close to the peak Ti:sapphire wavelength, and Cr\(^{4+}\):YAG, which lasers around 1.5 \(\mu\)m, an important communication wavelength. Cr:forsterite lasers, operating at about 1.2 \(\mu\)m, can be frequency doubled to the visible region and have been used for imaging applications (see section 5.2). Furthermore, passively mode-locked frequency-doubled erbium-doped fiber lasers have been developed commercially. These lasers operate between 1530 and 1610 nm and efficient frequency doubling to 765–805 nm is possible in periodically poled nonlinear crystals (i.e. these lasers can be used in place of Ti:sapphire for many applications).\(^{(28)}\) They have the advantage of being cheap and extremely compact since they do not require complicated dispersion-compensation schemes, owing to the soliton nature of the pulses supported in the fiber. They can also be pumped using cheap large-area telecommunications-standard laser-diode sources. Unfortunately, the pulse duration is limited to a minimum of about 100 fs.

### 2.2 Dispersion and Pulse Broadening

A bandwidth-limited pulse has a spectral width given by the Fourier transform of its time-domain profile. Consequently, a 10-fs full width at half-maximum (fwhm) Gaussian pulse centered at 800 nm has a bandwidth of 94 nm (1466 cm\(^{-1}\)). When a short pulse travels through a dispersive medium, the component frequencies are separated in time. Figure 2(a) and (b) shows the effect of dispersion on a Gaussian pulse traveling through a piece of glass. There are two points to note. First, the center of the pulse is delayed with respect to a pulse traveling in air. This is usually called the group delay, which is not a broadening effect. Second, normally dispersive media such as glass impose a positive frequency sweep or “chirp” on the pulse, meaning that the blue components are delayed with respect to the red.

In order to get a physical feel for the effect of the chirp, it is common to consider the phase shift as a function of frequency \(w\). The phase, \(\varphi(w)\) can be developed as a power series about the central frequency \(w_0\), assuming the phase varies only slowly with frequency according to Equation (1):

\[
\varphi(w) = \varphi(w_0) + (w - w_0)\varphi'(w_0) + \frac{1}{2}(w - w_0)^2\varphi''(w_0) + \frac{1}{6}(w - w_0)^3\varphi'''(w_0) + \cdots
\]

where (Equation 2):

\[
\varphi'(w_0) = \frac{\partial \varphi}{\partial w} \bigg|_{w=w_0}, \quad \varphi''(w_0) = \frac{\partial^2 \varphi}{\partial w^2} \bigg|_{w=w_0},
\]

\[
\varphi'''(w_0) = \frac{\partial^3 \varphi}{\partial w^3} \bigg|_{w=w_0}, \text{ etc.}
\]

\(\varphi'\) is the group delay, \(\varphi''\) the group delay dispersion (GDD) [or group velocity dispersion (GVD)] and \(\varphi'''\)
and $\psi''''$ are simply the third-order dispersion (TOD) and fourth-order dispersion (FOD).

For the sake of simplicity, consider a transform-limited Gaussian pulse with a central frequency $\omega_0$ and a pulse width (fwhm) $\tau_m$. Then its electric field, $E_{in}$, takes the form (Equation 3)

$$E_{in}(t) = E_0 \exp \left(-\frac{2\ln 2}{\tau_m^2} t^2 + i\omega_0 t \right)$$

The electric field after traveling through a dispersive medium can be found by transforming $E_{in}$ to the frequency domain and adding the components from the phase expansion $\varphi(w)$ in Equation (1) before transforming back. If we assume only a contribution from the GDD term, the electric field $E_{out}$ is given by Equation (4):

$$E_{out}(t) = E_0 \exp \left(i(\omega_0 t - \varphi) - \Gamma(t - \varphi)^2 \right)$$

where (Equation 5)

$$\Gamma = \frac{\tau_m^2}{2\ln 2} + 2\psi''''^{-1}$$

The effects of this dispersion are twofold. First, by inspection of the Gaussian part of $E_{out}$, $\tau_{out}$ is analogous to $\tau_m$ from $E_{in}$ and is broadened with respect to the input-pulse width by a factor (Equation 6)

$$\frac{\tau_{out}}{\tau_m} = 1 + \frac{\psi''''}{16(\ln 2)^2}$$

Second, a frequency sweep is introduced in the output pulse (because the expression in Equation (5) is complex) with a sign that is opposite to that of $\varphi''$.

The GDD, $\psi''''_m$, due to material of length $l_m$, is related to the refractive index of the material, $n(\lambda)$, at the central wavelength, $\lambda_0$, through its second derivative with respect to wavelength (Equation 7):

$$\psi''''_m = \frac{\lambda_0^4 l_m}{2\pi c^2} \frac{d^2 n(\lambda)}{d\lambda^2}$$

Figure 3(a) shows the variation of refractive index with wavelength for some common materials: (A) fused silica, (B) Schott BK7, (C) Schott SF10 and (D) sapphire. The points are measured values and the lines are fits to Sellmeier equations. (b) The GDD for 1 mm of material derived from the fits.

Figure 4 Gaussian pulse width before and after 10 mm of fused silica (solid line), corresponding to one or two optical components. The broadening is due to GDD.

If we consider a pulse of around 100 fs in duration, the effect is minimal but visible. However, a 10-fs pulse is broadened by more than a factor of 10!
A good understanding of dispersion is essential in order to deliver a short pulse to the sample and careful control of the phase shift is necessary. Fortunately, a number of designs using prism and grating pairs have been devised whereby this can be achieved. The two most important schemes are shown in Figure 5(a) and (b). The Ti:sapphire oscillator we discussed above uses the prism pair. This arrangement creates a longer path through the prism material for the red wavelengths compared with the blue, introducing a negative dispersion. Provided that the prism separation, $l_p$ (defined tip to tip), is sufficiently large, the positive dispersion of the material can be balanced. The prism apex angle is cut such that at minimum deviation of the center wavelength, the angle of incidence is the Brewster angle. Here, the Fresnel reflection losses for the correct linear polarization are minimized and the system is essentially loss free. The second scheme is the parallel-grating pair and, again, a longer path is created for the red over the blue. Grating pairs (Figure 6) introduce negative GDD at very modest separation leading to compact designs but suffer from losses of close to 50% in total. Both prism and grating pairs are used in a double-pass arrangement to remove the spatial dispersion shown in the diagram.

Expressions for calculating the dispersion are given in Table 1. The equations look a little daunting but the dispersion can be modeled easily on a personal computer. To illustrate this point, Figure 7 shows the total GDD and TOD arising from 4.75 mm of sapphire balanced against a silica prism pair separated by 60 cm. This is typical of a Ti:sapphire oscillator. The net GDD is nearly zero at 800 nm but the net TOD remains negative at the same wavelength. In fact, it is a general observation that prism compressors overcompensate the third-order term. The greater the dispersion of the glass, the less distance is required, but the contribution of the third-order term increases. Experimentally, there must usually be a compromise between prism separation and material.

Grating pairs are important in amplification and will be considered in more detail below. Significantly, however, the sign of the third-order contribution from the grating pair is opposite to that of the prisms, allowing a combined approach to dispersion compensation, which has been used to compress pulses in the 5-fs regime. It can be more useful to think in terms of the total GDD versus wavelength with a view to keeping the curve as flat and as close to zero as possible across the full bandwidth of the pulse.

Mirror coatings have been developed which can provide second- and third-order compensation. This so-called “chirped” mirror reflects each wavelength from a different depth through the dielectric coating, which is made up of multiple stacks of varying thickness. In combination with a prism pair, this technique has been as successful as the grating/prism combination without the associated losses. This type of system will become more common as the mirrors, tailored to individual requirements, become available commercially.
The accumulated phase in a double-pass prism compressor (see Figure 5a) is
\[ \psi(w) = \frac{2nw_0}{c} \cos \left( \frac{\psi_2^{\text{bluest}} - \psi_2}{2} \right) \]  
(8)
where \( \psi_2 \) is the (frequency-dependent) exit angle, \( \psi_2^{\text{bluest}} = \psi_2(w^{\text{bluest}}) \) is the exit angle of the shortest-wavelength light transmitted by the prism pair:
\[ \psi_2(w) = \arcsin \left[ n \sin \left[ \alpha - \arcsin \left( \frac{\sin \psi_1}{n} \right) \right] \right] \]  
(9)
where \( n \) is the (frequency-dependent) refractive index of the prism material, \( \psi_1 \) is the (frequency-independent) angle of incidence on the first prism and \( \alpha \) is the prism top angle. If the prism compressor is designed for frequency \( w_{\text{design}} \):
\[ \alpha = 2 \arcsin \frac{1}{1 + n_{\text{design}}^2} \]  
(10)
\[ \psi_1 = \arcsin \frac{n_{\text{design}} \sin \alpha}{2} \]  
(11)
where \( n_{\text{design}} \) is the refractive index of the prism at the design wavelength. Expressions for the group delay, GVD, TOD and FOD can be obtained by taking derivatives of Equation (8).

The group delay in a grating compressor/stretcher (see Figures 5b and 6) is
\[ \frac{d\psi}{dw} = \frac{P}{c} \]  
(12)
where the optical pathlength is
\[ P = L \frac{1 + \cos \theta}{\cos(\gamma - \theta)} \]  
(13)
\[ \theta(w) = \gamma - \arcsin \frac{2\pi c}{wd} - \sin \gamma \]  
(14)
with \( \gamma \) the angle of incidence on the first grating and \( d \) the groove frequency. In the case of a grating compressor, \( L = l_g \). In the case of a grating stretcher, \( L = 2(l_g - f) \cos \gamma \).

Expressions for the GVD, TOD and FOD can be obtained by taking derivatives of Equation (12). For a double-pass grating compressor/stretcher, the analytical expression
\[ \frac{d^2\psi}{dw^2} = -\frac{\lambda^2 L}{\pi c^2 d^2} \left[ 1 - \left( \frac{\lambda}{d} - \sin \gamma \right)^2 \right]^{-3/2} \]  
(15)
is found, where \( \lambda \) is the wavelength.

The accumulated phase in material is
\[ \psi(w) = \frac{wn_m}{c} \]  
(16)
where \( l_m \) is the length of the material. Expressions for the group delay, GVD, TOD and FOD can be obtained by taking derivatives of Equation (16). An analytical expression for the GVD is
\[ \frac{d^2\psi}{dw^2} = \frac{\lambda^2 l_m}{2\pi c^2 d \lambda^2} \]  
(17)

Expressions (Equations 8–17) for the dispersion for material, prism and grating pairs

2.3 Chirped-pulse Amplification

The amplification of nanojoule-level femtosecond pulses to the millijoule level and above is complicated by the extremely high peak powers involved. A 1-mJ 20-fs pulse focused to a 100-\( \mu \)m spot size has a peak fluence of \( 5 \times 10^{12} \text{ W cm}^{-2} \). The damage threshold of most optical materials is only a few gigawatts per square centimeter, 1000 times lower. The problem is overcome by stretching the pulse in time using dispersion to advantage. This is followed by amplification and subsequent recompression to the original pulse duration. This technique also has the benefit of eliminating unwanted nonlinear effects in the amplifier materials. A diagram showing the principle of chirped-pulse amplification (CPA) is shown in Figure 8.

The pulse stretcher is a variation of the grating pair described above. A unity-magnification telescope is placed between two gratings in an antiparallel rather than parallel geometry. This reverses the sign of the dispersion.
of the grating pair but otherwise the mathematical expressions given in Table 1 are identical.

The stretching factor is defined by the effective grating separation \( L = 2l_g - f \), where \( f \) is the focal length of the lens and \( l_g \) the distance from the lens to the grating. Typically, the pulse duration is increased to 100 ps or more for efficient extraction of the stored energy. When \( l_g \) is equal to \( f \), there is no dispersion, and when \( l_g \) becomes larger than \( f \), the dispersion changes sign. In practice, the lenses are replaced by a single spherical or parabolic mirror in a folded geometry, which eliminates chromatic aberration and allows gold-coated holographic gratings to be used near their most efficient Littrow angle of incidence, \( \text{arcsin}(\lambda_c/2d) \), where \( \lambda_c \) is the central wavelength and \( d \) the line separation of the grating. Other more sophisticated stretcher designs, one for example based on an Offner triplet,\(^{33}\) have been made but are outside the scope of this discussion. Ignoring the amplifier for now, the pulse is recompressed using an identical parallel grating pair separated by \( 2l_g \).

CPA technology developed rapidly during the 1990s. Solid-state materials usually have long upper-state radiative lifetimes compared with laser dyes. The large saturation fluence (1 J cm\(^{-2}\)) and long storage time (3 \( \mu \)s) of Ti:sapphire make it an ideal amplifier gain material. Here we shall consider two basic schemes, the regenerative and the multipass amplifier. These operate either at 10–20 Hz, pumped by a standard Q-switched Nd:YAG laser giving up to 100 mJ at 532 nm, or at 1–5 kHz pumped by an intracavity-doubled acousto-optically modulated CW Nd:YLF laser, which usually provide more than 10 W at 527 nm in a 200-ns pulse. These pump lasers are normally flash-lamp pumped but diode-pumped equivalents have appeared commercially in recent months. A good spatial mode quality is essential and a clean top-hat profile is ideal.

Figure 9(a) and (b) shows two arrangements for regenerative amplification. The arrangement in Figure 9(a) is often used at 1 kHz.\(^{34}\) Briefly, a single vertically polarized pulse from the oscillator, stretched to \( \sim 100 \) ps, is injected into the amplifier using a fast-switching PC. This is performed by stepping the voltage in two stages, first by a quarter wave, in order to trap the pulse in the amplifier cavity, and then up to a half wave for ejection. Typically, the pulse makes around 12 round trips in the cavity before the gain is saturated. A FR is used to isolate the output pulse from the input. The arrangement in Figure 9(b)\(^{35}\) differs in two respects. First, the focusing in the cavity is relaxed in order to remain near the saturation fluence for the more energetic pulses at 10 Hz. Second, the PC is used to switch the pulse in and out while it is traveling in opposite directions. This has two great advantages for short pulses: (1) there is only one pass made through the Faraday isolator, which has extremely large dispersion and only a limited spectral bandwidth, and (2) it is only necessary to apply a half-wave voltage to the PC at the moment the pulse is switched in or out of the cavity. Again, this is to avoid bandwidth-limiting effects.

An alternative and perhaps more straightforward design for amplification of femtosecond pulses is based on the multipass scheme that has been used in the past with dye amplifiers. One of the best arrangements for use at kilohertz repetition rates\(^{36}\) is shown in Figure 10 and an example of a 10-Hz system can be found in a paper by Chambaret et al.\(^{37}\) A PC is used to inject a single pulse from the 80-MHz pulse train into the amplifier, where it is allowed to make about eight passes with a slight offset at each cycle before being picked off and ejected. The

![Figure 9](image1.png)  
**Figure 9** Two schemes for regenerative amplification. The design in (a) is often used for kilohertz repetition rate amplifiers and that in (b) at a 10–20-Hz repetition rate. The Ti:sapphire rod is usually ca. 20 mm long and doped for 90% absorption. TFP, thin-film polarizing beamsplitter; PC, Pockels cell; FR, Faraday rotator; \( \lambda/2 \), half-wave plate. In (a), M1 is 150 mm radius of curvature, M2 is flat and M3 is flat. In (b) M1 is \( -20 \) m and M2 is \( +10 \) m.

![Figure 10](image2.png)  
**Figure 10** Multipass-amplifier arrangement. M1, M2 are 1-m radius of curvature mirrors and M3 is flat and up to 15 cm wide. A PC and a pair of polarizers are used to inject a single pulse into the amplifier.
pulses incur significantly less loss in these arrangements, accrues much less chirp and only one pass is made through the PC. There is also no need for a Faraday isolator.

Additional power-amplification stages may be added to increase the pulse energy further. The ring configuration can be modified by arranging for the beams to cross away from the focus to achieve a different saturation fluence. In this configuration, 4 W after recompression at 1 kHz has been obtained.\(^\text{(38)}\) At kilohertz repetition rates, the presence of a thermally induced refractive index change across the spatial profile of the beam must be avoided in order to achieve diffraction-limited output. This is achieved either by cooling to 120 K where the thermal properties of sapphire are much improved\(^\text{(39)}\) or by using the lens to advantage.\(^\text{(40)}\) At lower repetition rates, the medium has time to recover and a thermal lens is usually not established. In this regime, power amplifiers can be added to the limit of available pump energy. An additional complication requires that short pulses of more than a few millijoules in energy must be recompressed under vacuum to avoid nonlinear effects and ionization of the air.

### 2.4 Pulse Recompression

Clearly, the amplification process introduces extra dispersion and one of the major considerations in system design is the recompression process. The naive approach is to add additional separation between the gratings in the pulse compressor and this is how the first systems were built. Unfortunately, the stretcher and compressor combination is the most dispersive part of the system and a mismatch between the two introduces vast third- and fourth-order contributions to the phase expansion. The easiest way to correct the TOD is to adjust the angle of incidence between the stretcher and compressor, which changes the third-order contribution. Figure 11 (line A) shows the net group-delay dispersion versus wavelength for the kilohertz regenerative amplifier discussed above. The GDD curve is essentially flat over only a narrow wavelength range although the GDD and TOD are zero simultaneously at the center wavelength. Table 2 shows the bandwidth (fwhm) of Gaussian pulses of different durations. Ideally, the GDD curve should be flat over perhaps twice the bandwidth to avoid phase distortions.

Recall that the third-order contribution from prism pairs has the opposite sign to gratings.\(^\text{(41)}\) This fact can be used to null the GDD, TOD and FOD terms and this is illustrated in Figure 11 (line B). The difference is dramatic and this system will support much shorter pulses at the expense of 2.4 m of pathlength between the SF18 prism pair.

Another method in the recent literature\(^\text{(42)}\) uses gratings of different groove density in the compressor compared with the stretcher balanced against additional round trips in the amplifier. This method, while better than the angular adjustment technique, is not as effective as the grating–prism combination approach, although it has found favor in commercial application owing to its inherent compactness. Typical parameters are a 1200 lines mm\(^{-1}\) grating in the stretcher at an angle of incidence of only 6° and 2000 lines mm\(^{-1}\) in the compressor at 57°, which is reasonably close to Littrow geometry (55°). Gratings with 2000 lines mm\(^{-1}\) are significantly more efficient than those with 1200 lines mm\(^{-1}\), giving improved throughput in the compressor. However, a combination of mixed gratings and a prism pair as shown in Figure 11 (line C) is a little better than matched gratings and prisms with the benefit of extra throughput and reduced prism separation without the need to balance the

---

**Figure 11** Solid line (A): the net GVD due to the stretcher–amplifier–compressor combination using 1200 lines mm\(^{-1}\) diffraction gratings. The difference between the angle of incidence in the stretcher compared to the compressor is 10.32° and the extra grating displacement is 69.4 mm. Dashed line (B): the same using 1200 lines mm\(^{-1}\) gratings in combination with an SF18-glass prism pair. The difference between the angle of incidence in the stretcher compared to the compressor is 3.4° and the extra grating displacement is 26.2 mm. The prism separation is 2.4 m. Dashed-dotted line (C): the same, using a 1200 lines mm\(^{-1}\) diffraction grating in the stretcher and an 1800 lines mm\(^{-1}\) grating in the compressor in combination with an SF10-glass prism pair. The angle of incidence in the stretcher is 13° and in the compressor 39°. Littrow is 41°. The prism separation is 1.65 m.

total dispersion with extra amplifier material. This system will support 20-fs pulses with little phase distortion.

2.5 Saturation Effects

The gain cross-section, \( \sigma_g \), is not constant as a function of wavelength. Since this appears as an exponent in calculating the total gain, successive passes through the amplification medium can lead to pulse spectral narrowing and a shift in the central wavelength. This limits the maximum bandwidth to 47 nm in Ti:sapphire.\(^{(38)}\) As the gain approaches saturation, the leading red edge of the pulse extracts energy preferentially and the spectrum will red shift. The maximum gain bandwidth can be achieved by seeding to the blue of the peak, allowing the gain to shift towards the maximum on successive passes. Second, by altering the gain profile by discriminating against the peak wavelengths using an etalon or a birefringent filter, termed regenerative pulse shaping, the theoretical limit can be overcome.\(^{(44)}\)

3 WAVELENGTH CONVERSION

Ultrafast lasers and amplifiers typically operate at a very limited range of wavelengths. For example, Ti:sapphire-based ultrafast lasers are tunable in the near-infrared (NIR) region from about 700 to 1000 nm but typically work best at about 800 nm. The high peak power of these lasers can be used, however, to convert the laser light to different wavelengths. In fact, in some cases ultrafast laser systems may be the ideal or only route to make radiation at certain wavelengths. Below, a series of techniques are described to convert femtosecond laser pulses at visible wavelengths to other wavelengths.

3.1 White-light Generation and the Optical Kerr Effect

At high intensities such as on the peak of an ultrashort laser pulse, the refractive index of any medium becomes a function of the incident intensity. This effect, which is often referred to as the optical Kerr effect (OKE),\(^{(45)}\) can be described by Equation (18):

\[
n(I) = n_0 + n_2 I + \cdots
\]

where \( n_0 \) is the normal refractive index of the medium and \( n_2 \) is the nonlinear refractive index. The nonlinear refractive index is very small, for example, in fused silica \( n_2 \approx 3 \times 10^{-16} \text{ cm}^2 \text{ W}^{-1} \). A laser pulse with center frequency \( \nu \) traveling through a medium of length \( L \) will acquire an optical phase \( \nu L n_2 / c \) and therefore the effects of the nonlinear refractive index will become important when this phase factor becomes comparable to a wavelength. As an example, consider the propagation of femtosecond pulses through an optical fiber. With a 9-\( \mu \)m fiber-core diameter (typical for communications-grade fiber), 10-nJ pulse energy and 100-fs pulse width, the peak power is 100 kW, corresponding to a power density of \( 1.5 \times 10^{11} \text{ W cm}^{-2} \). If the length of the fiber is 1 cm, the optical pathlength changes by \( Ln_2 I = 472 \text{ nm} \) or half a wavelength. From this calculation, it can be seen that the OKE can have a significant effect on a femtosecond pulse traveling through a medium. For pulses with energies in the order of millijoules or higher, even the nonlinear refractive index of air becomes important.

To understand how the OKE can modify the spectral properties of an ultrashort pulse, one has to consider how the nonlinear refractive index modifies the optical phase of the pulse. The electric field of a laser pulse traveling in the \( x \) direction can be written as Equation (19):

\[
E(t) \cos(\omega t - kx)
\]

where \( k = \nu n/c \) is the wavenumber. Since the wavenumber depends on the (nonlinear) refractive index of the medium, the pulse will acquire a time-dependent phase induced by the Kerr effect. Inserting Equation (18) into Equation (19) and performing a Taylor expansion around the peak of the ultrashort pulse, one finds Equation (20)

\[
E(t) \cos[(\omega + \xi t)t - kx]
\]

where \( \xi \) depends on the nonlinear refractive index, the pulse width and peak power, and the distance traveled. Consequently, the nonlinear refractive index induces an approximately linear frequency sweep (or chirp, see section 2.2 and Figure 12) on the pulse. In other words, the spectrum of the pulse has broadened owing to the nonlinear interaction. If a single pulse modifies its own characteristics in this way, the effect is often referred to as self-phase modulation. If one pulse modifies the effective refractive index causing a second pulse to change its characteristics, this is referred to as cross-phase modulation.

The spectral broadening induced by the nonlinear refractive index is extremely useful in spectroscopic applications. For example, an 800-nm femtosecond pulse can be sent through a short length of fiber or through a few millimeters of glass or sapphire to produce a broadband output pulse. Often there will be significant power at wavelengths ranging from 400 nm to 1.6 \( \mu \)m. For this reason, such spectrally broadened pulses are referred to as white-light continuum pulses. The white-light continuum generated in a fiber has been used to generate some of the world’s shortest pulses of around 5 fs.\(^{(46,47)}\) A white-light continuum pulse is an ideal seed for an optical parametric amplifier (see section 3.3).
An implication of the nonlinear refractive index is self-focusing or defocusing. As a laser beam is typically more intense in its center, the nonlinear change of the refractive index will be strongest in the center. As a result, the medium will act as an intensity-dependent lens. In a set-up in which the sample is translated through the focus of a beam, this effect can be used to measure the nonlinear refractive index of a sample quickly. Self-focusing is the basis of the Kerr lens mode locking (KLM) effect used in ultrashort lasers (see section 2.1). Self-focusing can become a run-away process leading to beam distortion and catastrophic damage to optical components. In white-light generation, self-focusing can result in the beam breaking up into multiple filaments that make the white-light output extremely unstable. It is therefore of the utmost importance to choose the incident power such that white light is generated without producing multiple filaments. For a 100-fs pulse, this usually means that the pulse energy should be limited to approximately 1 µJ.

3.2 Generation of Ultraviolet and X-rays

The very high peak power that can be achieved with femtosecond pulses means that in principle nonlinear frequency conversion should be very efficient. It should be straightforward to use second-harmonic generation (SHG), third-harmonic generation (THG) and fourth-harmonic generation (FHG) to produce femtosecond pulses in the near- to deep-ultraviolet (UV) region. However, the group velocity of the pulses (see section 2.2) depends on the center wavelength and changes significantly as the UV region is approached. For example, in a 1-mm β-barium borate (BBO) crystal (suitable for harmonic generation down to about 180 nm) the difference in group delay between the fundamental and the fourth harmonic is 3.3 ps (see Table 3). Depending on the set-up, this implies that the conversion efficiency is very low or the pulses produced are very long. Therefore, when UV pulses are produced, it is extremely important to use the thinnest possible nonlinear crystals. As a rough guide, one should choose the thickness of the crystal such that the group-delay difference between the fundamental and the harmonic is about equal to or less than the width of the pulse. An efficient harmonic-generation set-up will also use multiple conversion steps and between steps readjust the relative time delay between the laser pulses at different wavelengths.

Most nonlinear crystals used for harmonic generation [BBO, lithium triborate (LBO), potassium dihydrogenphosphate (KDP), etc.] are opaque in the deep-UV region. Very high harmonic generation in low-pressure gases has been used successfully to generate deep-UV and soft X-ray pulses. It was recently shown that a glass capillary could be used to modify the phase-matching condition for coherent soft X-ray generation. Using this set-up, femtosecond pulses at 800 nm were converted to the 17–32-nm wavelength range (~30th harmonic) with about 0.2 nJ energy per harmonic order. A similar set-up was used to mix 800- and 400-nm pulses to produce 8-fs pulses at 270 nm. Extremely short (5 fs) amplified laser pulses have been used to generate X-rays (~4 nm) in the water window by harmonic generation in a gas jet.

The advantage of very high harmonic generation is that the X-rays are generated in a well-collimated beam. The disadvantage is that it has not yet been shown to be possible to generate hard X-rays with wavelengths smaller than a molecular bond length.

Electron impact sources could generate femtosecond hard X-rays if high-charge, high-energy femtosecond electron bunches were available. Even so, electron impact sources have the disadvantage that the X-rays are emitted in a 2π solid angle, which makes their brightness typically very low. Therefore, these sources are difficult to use in diffraction experiments although not strictly impossible. Very high-power laser pulses [peak powers of the order of 1 TW (10^{12} W)] can be used to generate laser-produced plasmas.\(^{(53)}\) Typically, a high-power laser pulse is used to evaporate a (metal) target and produce a plasma by stripping electrons off the atoms with multiphoton ionization.\(^{(54)}\) Recombination of these electrons with the ions results in the emission of hard X-ray pulses (wavelengths of the order of 1 Å). Very recently, it has been shown that reverse Thompson scattering of terawatt laser pulses off a high-energy (50 MeV) electron beam can be used to produce hard X-rays (0.4 Å).\(^{(55)}\) However, only 10^4 X-ray photons were generated per laser shot, resulting in about one diffracted X-ray photon per shot in diffraction off Si (111).

### 3.3 Optical Parametric Amplifier for Infrared Generation

The infrared (IR) region of the spectrum is very important for the sensing of a great variety of (transient) molecular species. Femtosecond IR pulses can be used to determine which bonds in a molecule break or form. The mid-IR fingerprint region is ideally suited to determine the presence of specific molecules in a sample. Therefore, a great deal of effort has been invested over the last decade to produce femtosecond pulses tunable in the near- and mid-IR regions. Most techniques in use now are based on parametric difference-frequency processes (see Figure 13a and b).\(^{(56)}\) In difference-frequency mixing, a strong femtosecond pulse at frequency \(\omega_1 + \omega_2\) mixes in a nonlinear crystal with a (weaker) pulse at frequency \(\omega_1\), to produce a new beam of femtosecond pulses at frequency \(\omega_2\). If the incident power at frequencies \(\omega_1\) and \(\omega_2\) is zero, a nonlinear crystal can produce these frequencies spontaneously in a process referred to as optical parametric generation (OPG). If the incident power at frequencies \(\omega_1\) and \(\omega_2\) is small but nonzero, the pump pulse at frequency \(\omega_1 + \omega_2\) can amplify the former frequencies in what is referred to as OPA. Since the peak power of a femtosecond pulse can be extremely high while the pulse energy is relatively low, one can produce enormous parametric gain without destroying the nonlinear crystal.

The frequencies or wavelengths that are produced in OPG or OPA depend on the phasematching condition, group velocity walk-off and the type of crystal used. Figure 13(b) shows materials that are commonly used for parametric generation in the IR region. BBO has a limited tuning range in the IR range (approximately 1.2–2.8 μm when pumped at 800 nm) but is very efficient owing to the small group-velocity walk-off and high damage threshold. KTP and its analogs rubidium titanyl phosphate and cesium titanyl phosphate (RTA and CTA) are not as efficient as BBO but allow the generation of femtosecond pulses at wavelengths as long as 3–4 μm. There is a variety of crystals suitable for generation of pulses in the mid-IR region such as AgGaS\(_2\) and GaSe. However, when these crystals are used to convert directly from the visible to the mid-IR, they suffer from enormous group velocity walk-off, (two-photon) absorption of the pump and very poor efficiency. Therefore, generating mid-IR pulses is typically performed in a two-stage

![Figure 13](attachment:figure13.png)
process, an OPA generates two NIR frequencies (e.g., 800 nm → 1.5 μm + 1.7 μm, for example, in BBO) followed by a difference frequency mixing stage (e.g., 1.5–1.7 μm → 12 μm, for example, in AgGaS2).

All known materials suitable as a nonlinear difference-frequency mixing crystal absorb strongly in the far-IR region. GaSe and AgGaSe2 have the longest wavelength cutoff of about 18 μm. In order to produce longer wavelengths, different techniques have to be used (see section 3.5). It has recently been shown that periodically poled crystals such as periodically poled KTP (57) can be used with great success to generate femtosecond IR pulses efficiently.

When femtosecond IR pulses are generated, they inevitably have a very large bandwidth, e.g. about 100 cm⁻¹ for a 100-fs pulse, which is clearly much larger than the line width of a typical vibrational transition. This does not mean that femtosecond IR pulses are useless for vibrational spectroscopy – quite the contrary! The IR pulse can be spectrally resolved after the sample. The recent availability of IR diode arrays and IR charge-coupled device (CCD) cameras means that an entire IR spectrum can be taken in a single laser shot. However, in time-resolved experiments, the broadband IR pulse can excite multiple transitions at once and one has to take account of this carefully in the theoretical analysis of experiments. (59)

3.4 Noncollinear Optical Parametric Amplification

Noncollinear optical parametric amplification (NOPA) is a technique used to generate sub-20-fs tunable visible and NIR pulses. (60) In a collinear geometry, the temporal output of parametric generators and amplifiers is restricted by group-velocity mismatch between the pump and the generated signal and idler fields. In a noncollinear arrangement, this effect can be overcome since only the projection of the idler group velocity onto the seed is important. By arranging the pump and seed incidence angles with respect to the phase-matching angle correctly, this group-velocity mismatch can be zeroed in some nonlinear crystals. A seed pulse, which is a single filament of white-light continuum generated in a 1-mm thick piece of sapphire, is amplified by the frequency-doubled output of a Ti:sapphire amplifier, in type I BBO cut at 31°. The sapphire must be cut such that the optical axis runs perpendicular to the cut face. Type I LBO is used to generate the second harmonic of the Ti:sapphire around 400 nm. The pump beam focused on to the BBO generates a cone of parametric superfluorescence (inset of Figure 14). When the angle of incidence at the crystal is correct, there is no appreciable spatial divergence of the superfluorescence. By directing the continuum seed beam along the cone axis, a large spectral bandwidth from the white light can be simultaneously phase matched. Adjustment of the relative delay between pump and seed and some control of the chirp on the continuum together change the center wavelength and bandwidth of the amplified light. One great advantage of this scheme is that relatively thick crystals can be employed (typically 2 mm), which results in high single-pass gain. The amplified output is then recompressed using a prism pair (BK7 separated by ~60 cm) yielding sub-20 fs visible pulses continuously tunable from 480 to ~700 nm. Pulses as short as 5 fs have been generated (62) using a prism–double chirped mirror recompression scheme, although the mirrors are unavailable commercially at the time of writing. Pumping with only 10 μJ of blue light, 2 μJ can be generated at the signal wavelength. If higher energy is available, a second amplification stage can be added and 10 μJ can be obtained for a 75-μJ pump. Using the same technique, extremely short NIR light can be generated in type II phase-matched BBO pumped at the Ti:sapphire fundamental.

3.5 Terahertz-pulse Generation and Detection

As described above, NIR and mid-IR pulses can be generated using parametric down conversion. However, down conversion cannot produce pulses with a wavelength longer than about 18 μm. Long-wavelength pulses can be generated (and detected) using so-called terahertz techniques. There are effectively two methods for generating subpicosecond terahertz (10¹² Hz) pulses: photodetection or optical rectification. In photodetection, a laser pulse incident on an absorbing semiconductor creates (real) charge carriers in the conduction band. Acceleration of these carriers in an electrical bias field gives rise to a transient photocurrent that radiates electromagnetic waves. In the far field the radiated electric field is given by \( E_E(t) \propto \frac{dJ_S(t)}{dt} \), where \( J_S(t) \) is the time-dependent surface current. This method is typically used...
in conjunction with an antenna structure (see Figure 15a and b), which allows an external bias field to be applied. An antenna structure ideally suited to be used with low-power mode-locked lasers was developed in the 1980s at Bell Laboratories\(^6\) and IBM,\(^6\) and is now the most common method for generating and detecting terahertz pulses. In such a set-up, two metal electrodes are laid down on a silicon or GaAs substrate, typically with a separation of \(100 \mu m\). A beam of femtosecond laser pulses is focused between the electrodes, in a spot with a diameter of a few micrometers. On the generation side, the metal electrodes are biased with a few tens of volts and the excitation by the pump laser triggers the emission of terahertz radiation. On the detection side, the incident terahertz beam accelerates carriers created by another visible beam, resulting in a measurable photocurrent. Since the visible beam has to be focused to a very tight spot in this method, only unamplified ultrafast lasers can be used. There is no overriding reason, however, why one should use such closely spaced electrodes. Large-aperture photoconducting antennas work very well for the generation of terahertz pulses when pumped by amplified pulses. The conversion efficiency is about 0.1%. With low repetition rate (10–1000 Hz) ultrafast laser systems, far-IR pulses with energies as high as 1 \(\mu J\) have been generated.\(^6\)

An external bias field is not strictly necessary for photoconductive generation of terahertz pulses, as real carriers generated by a visible laser pulse can be accelerated in the field of the depletion layer of the semiconductor. This surface field will accelerate the carriers perpendicular to the surface of the semiconductor and hence the terahertz oscillating dipole will be perpendicular to the surface. Therefore, terahertz radiation generated through this effect is only observed if the angle of incidence of the exciting visible laser beam is nonzero. Typically, the effect maximizes at the Brewster angle.

Optical rectification is distinct from photoconduction, in that the visible exciting beam creates virtual rather than real carriers. A more appropriate way to describe this is that the second-order susceptibility, \(\chi^{(2)}\), of the crystal is used for difference-frequency mixing. Thus, the second-order polarization can be written in the time domain as Equation (21):

\[
P_{\text{THz}}^{(2)}(t) = e_0 \chi^{(2)} E_{\text{VIS}}(t) E_{\text{VIS}}(t)
\]

which shows that the electric field of the terahertz pulse has the same shape as the intensity envelope of the visible exciting pulse. In the last few years, it has been discovered that optical rectification is an efficient method for generating terahertz pulses if used appropriately. Since a subpicosecond terahertz pulse has a spatial length comparable to its center wavelength, it travels through a material at its phase velocity. Therefore, for optimum conversion from visible to far-IR wavelengths, one has to match the group velocity of the visible pulse with the phase velocity of the terahertz pulse.\(^6\) This condition is met in some zinc blende, large band-gap semiconductors such as ZnTe and GaP when the exciting laser has a center wavelength of ca. 800 nm.

The inverse of optical rectification is electrooptic sampling: a terahertz pulse incident on an electrooptic crystal such as ZnTe will induce a birefringence through the Pockels effect. An ultrafast visible probe pulse with a variable delay copropagating through the same crystal will experience a retardation that can be retrieved with balanced detection. Scanning the relative time delay of

\[E(t) \text{(arb. units)}, \text{Frequency (cm}^{-1})\]

\[\text{Delay (ps)}\]
the probe pulse, one can record a time-domain trace of the electric field of the terahertz pulse. Using this method, signal-to-noise ratios, defined as the ratio of the terahertz pulse peak to the noise background, as high as $10^7$ have been reported. However, the signal-to-noise ratio with which one can measure the peak of the terahertz pulse is typically of the order of $10^2$–$10^3$ in 100 ms. An exciting new variation on this technique is the use of a chirped probe pulse. A femtosecond pulse at 800 nm can be stretched and chirped to tens of picoseconds using a grating pair. If this chirped pulse is used in the electrooptic sampling process, there will be a relationship between wavelength and relative time delay. Thus, detection of this probe pulse with a spectrometer and diode-array detector allows one to measure the entire terahertz pulse shape in a single laser shot.

As rectification and electrooptic sampling are nonresonant effects, the minimum duration of the terahertz pulses that can be generated or detected is limited only by the thickness of the crystal scaled with the difference in phase and group velocity. Thus, with ca. 10–15-fs exciting pulses at 800 nm, it was shown that terahertz pulses could be generated with detectable frequencies as high as 70 THz. At these large bandwidths, it is unavoidable that the t-ray spectrum will overlap with a photon absorption band in the generating and detecting crystals, leading to large oscillations in the terahertz field trailing the main peak.

The current record highest detectable frequency for a terahertz pulse is $\sim 70$ THz, but there is no reason to believe that this could not be improved upon. Using the simple time–bandwidth relation, $\Delta \nu \Delta \tau = 0.32$, it follows that with the shortest visible pulses achievable, ca. 4–5 fs, usable power at frequencies from 0 to 160 THz ($\lambda = 1.8 \mu m$) could be achieved. As femtosecond lasers continue to shrink in size, it may be expected that ultrafast terahertz devices may well take over from Fourier transform infrared (FTIR) spectrometers as general-purpose IR spectrometers. As an entire terahertz time-domain trace can be acquired in a single shot, these devices would combine the reliability and accuracy of FTIR spectrometry with real-time speeds. The most significant aspect of ultrafast terahertz pulses, however, is that they are synchronized with visible or UV pulses, allowing time-domain spectroscopy.

3.6 Femtosecond Electron Pulses

Very short (picosecond to femtosecond) electron pulses are useful for a variety of applications. For example, picosecond electron pulses have been used as a probe pulse for determining the time-dependent structure of molecules undergoing chemical reactions (see section 5.3). However, such pulses might also be used as a seed for electron accelerators or for the generation of femtosecond X-ray pulses. Current technology for generating femtosecond electron pulses is based on experiments done in the past with picosecond and nanosecond laser pulses. A UV laser beam is used to irradiate a metal target. If the photon energy is higher than the work function of the metal (typically 4–5 eV for common transition metals such as gold, silver or tungsten), electrons are ejected into the vacuum through the photoelectric effect. These emitted electrons are electrostatically extracted and accelerated into a narrow beam. In recent experiments (see section 5.3), this technique has been brought into the subpicosecond domain. The main problem in maintaining the time resolution is the space-charge effect: nonrelativistic electrons repel each other through Coulomb repulsion. It is therefore of the greatest importance to accelerate the electrons as quickly as possible and to keep the number of electrons per pulse as low as possible. Thus, it was seen in an experiment that for a 100-µm laser spot size on the photocathode, the electron pulse would broaden to about 15 ps when there were 1000 electrons in the pulse. When the number of electrons per pulse was reduced to 100, the pulse width was less than 1 ps. There is no fundamental reason why one could not work with ten or even one electron per pulse and therefore it should be possible to achieve electron-pulse durations in the order of tens of femtoseconds. Of course, to achieve a reasonable signal-to-noise ratio in an experiment, the pulse repetition rate should be high. Such pulses will be of great value in time-dependent molecular structure determination.

4 TIME-RESOLVED EXPERIMENTS

Most electronic devices cannot measure transients much faster than about 1 ns. Although there are specialized electronic devices such as streak cameras that may be able to resolve picosecond or even hundreds of femtosecond transients in real time, in most cases it makes more sense to look for alternative detection techniques. The techniques that are used most frequently are based on auto- or cross-correlation of two beams of femtosecond pulses (see Figure 16a). If the sample is a nonlinear crystal used for sum-frequency generation, this technique can be used to determine the shape and relative arrival time of two short pulses. If the sample contains molecules or atoms that resonantly absorb the incident radiation, the experiment is a pump–probe experiment.

4.1 Auto- and Cross-correlation

In an autocorrelator, an incoming beam of pulses is split in two. One beam travels through an optical path with
two-photon absorption in a photodiode may be used to provide the required second-order response.\(^{(75)}\) The averaged measured auto- or cross-correlation signal then has the form (Equation 22)

\[
I_{\text{cross}}(\tau) \propto \chi^{(2)} \frac{1}{2} I_{w1}(t)I_{w2}(t - \tau) \, dt \tag{22}
\]

where \(\chi^{(2)}\) is the second-order susceptibility of the nonlinear crystal and \(\tau\) is the relative delay time \(t_1 - t_2\) between the two pulses. Of course, the cross-correlation signal consists itself of a train of femtosecond pulses but since one is only interested in the average signal as a function of the relative time delay, no fast detector is required. Since the nonlinear crystal is chosen such that it does not exhibit any time-dependent processes of its own, the cross-correlation signal as a function of time delay is proportional to the shape of the incoming pulses. For example, in the case of an autocorrelation of a pulse with a Gaussian envelope, the autocorrelation signal as a function of delay has itself a Gaussian shape. In this example, one can measure the fwhm of the autocorrelation signal and find the width of the intensity envelope of the pulse by multiplying by 0.71. The value of the conversion factor depends on the pulse shape and a list of conversion factors can be found in Table 4. In practice, it may be wise to use nonlinear curve fitting to determine the pulse shape and corresponding conversion factor.

Clearly, the auto- or cross-correlation signal contains limited information about the pulse shape. For example, an asymmetric pulse shape will go undetected in an autocorrelation. More serious is that an autocorrelation will provide almost no information about possible chirp on the pulse (see section 2.2). If the pulse is chirped, the autocorrelation will be broader than might be expected from the pulse spectrum. Table 4 has a column with time–bandwidth products, that is, the product of the fwhm of the intensity envelope of the pulse in the time domain and the frequency domain. However, checking that the time–bandwidth product is close to that expected for a given pulse shape is not a very good method of making sure that the pulse is chirp free.

A better method for detecting chirp is the measurement of an interferometric autocorrelation and is taken by overlapping the two input beams. The correlation signal is now much more complicated\(^{(77)}\) and oscillates at frequencies corresponding to the laser fundamental and second harmonic. Since the second-harmonic intensity is proportional to the square of the incident intensity, the detected second-harmonic intensity as a function of delay is (Equation 23)

\[
I_{2w}(\tau) = \frac{1}{T} \int_{-T/2}^{T/2} [E(t) + E(t - \tau)]^2 \, dt \tag{23}
\]
where $T$ is the measurement time, and $T \gg \tau$. Figure 16(b) shows an experimental interferometric autocorrelation trace of a 25-fs 800-nm pulse. If the pulse is bandwidth limited, the interferometric autocorrelation signal yields a ratio between peak and background of 8:1. Linear chirp (caused by GDD) is clearly visible as the peak-to-background ratio is much less than 8:1. Nonlinear chirp (caused, for example, by residual TOD) is clearly visible as the peak-to-background ratio is 8:1. Linear chirp (caused by GDD) is clearly visible as the peak-to-background ratio is much less than 8:1. Linear chirp (caused by GDD) is clearly visible as the peak-to-background ratio is much less than 8:1. Linear chirp (caused by GDD) is clearly visible as the peak-to-background ratio is much less than 8:1.

Another useful technique for characterizing femtosecond pulses is called frequency-resolved optical gating (FROG)\(^{(78)}\) with which both the intensity and phase of a femtosecond pulse can be determined. The critical feature of FROG is that it measures the (second- or third-order) autocorrelation as a function of both time delay and frequency (see Figure 17). As before, a beam of femtosecond pulses is split in two and recombined on a nonlinear crystal. In this case, the two beams are focused on the nonlinear crystal using a cylindrical lens. As a result, different positions on the crystal correspond to different relative delay times. If the crystal produces the second harmonic of the incident beams, the emergent beam will have the autocorrelation trace spatially encoded on to it. If the signal beam is sent through a spectrometer, a two-dimensional detector such as a CCD camera can be used to measure a signal that depends on delay in one direction and frequency in the other. Various nonlinearities can be used with the FROG technique, such as SHG and self-diffraction (effectively the OKE in a piece of glass; see section 3.1).

In the polarization-gate arrangement of self-diffraction,\(^{(79)}\) the probe pulse $E(t)$ passes through crossed polarizers and is gated at the nonlinear medium by the gate pulse $E(t - \tau)$, which has a 45° relative polarization. A cylindrical lens focuses each beam to a line in the sample (e.g. a piece of glass) so that the delay varies spatially across the sample. Consequently, at the spectrometer, the delay $\tau$ varies along the slit, whereas the frequency $\nu$ varies in a direction perpendicular to this. For such an arrangement, the resulting signal-pulse electric field is given by Equation (24):

$$E_{\text{sig}}(t, \tau) \propto \chi^{(3)} E(t) |E(t - \tau)|^2$$

(24)

where $\chi^{(3)}$ is the third-order susceptibility of the sample (i.e. the strength of the OKE). The FROG trace can be considered a “spectrogram” of the field $E(t)$ as the signal intensity is given by Equation (25):

$$I_{\text{FROG}}(w, \tau) \approx \int_{-\infty}^{\infty} E(t) g(t - \tau)e^{-i\omega t} dt$$

(25)

where the variable-delay gate function $g(t - \tau)$ is equal to $|E(t - \tau)|^2$. This quantity can be thought of as a gate that chooses a slice of the time-varying signal pulse.

At each delay, the signal consists of different frequency components, so the gate function builds up a spectrum of the pulse for every value of $\tau$. For a transform-limited pulse, it is expected that only frequencies within the

Figure 17 Experimental arrangement for single-shot FROG. Two beams of femtosecond pulses are focused with a cylindrical lens on to a nonlinear crystal, e.g. one that generates the second-harmonic of the input beam. Because of the focusing geometry, the position on the nonlinear crystal corresponds directly with time delay. This allows one to measure the correlation trace as a function of both time and frequency.

Table 4 Second-order autocorrelation functions and time–bandwidth products for various pulse-shape models\(^{(78)}\) where $\tau_p =$ pulse width (fwhm), $\tau_G =$ autocorrelation width (fwhm) and $\Delta \nu =$ spectral width (fwhm)

</table>
bandwidth of that pulse would be resolved and that the instantaneous frequency remains the same at each point in time. However, for a chirped pulse, where lower frequencies lead higher ones or vice versa, the frequency-resolved trace will be considerably different, since the instantaneous frequency is a function of time. Since the phase of the signal pulse is contributed only by \( E(t) \) \( E(t - \tau) \) appears as the square, so all phase information is lost, the phase can be retrieved from a FROG trace. This is achieved using an iterative Fourier-transform algorithm.

Ultrashort pulse characterization techniques generally require instantaneously responding media. The polarization gate geometry FROG technique uses the electronic Kerr effect, which is accompanied, however, by a Raman-ringing effect. The slower nuclear motion of the material must therefore be considered in the iterative algorithm used to retrieve the pulse phase and intensity. The pulse-retrieval algorithm can be modified\(^{(80)}\) by including terms due to the slow response of the medium in the signal-field equation. Such problems with a slow response of the correlating medium can be avoided by using two-photon absorption in a diode.\(^{(75)}\)

### 4.2 Pump–Probe Techniques

Most ultrafast spectroscopy experiments use the pump–probe technique, which is very similar to the cross-correlation technique described above. In pump–probe spectroscopy the pump beam is typically much stronger than the probe beam, the two beams have a different center wavelength (or the probe may not even be a laser beam), and the sample tends to be more interesting.

As in the cross-correlation technique, the femtosecond time resolution is obtained by sending one of the beams through a motor-driven optical delay line. The (relatively) strong pump beam initiates some process of interest, e.g. a chemical reaction. The probe beam, entering the sample later, will be amplified, attenuated or refracted because of the changes taking place in the sample. There are so many variations of this scheme and literally thousands of experimental examples that it would be pointless to list them all. Therefore, two examples of the pump–probe technique will be described in some detail here to convey the general idea.

Figure 18 shows a very typical pump–probe spectroscopy set-up. A relatively strong pump beam is sent through an optical delay line (DL1) and focused into the sample (S). A small fraction of the pump beam is split off and converted to another wavelength. In this example, a white-light continuum is generated as a probe, which is sent through another optical delay line (DL2) and into the sample. After the sample, the white-light probe is spectrally resolved by a spectrometer (SP) before being detected by a “slow” detector (D).

A variation on the pump–probe technique is the photon echo.\(^{(56)}\) Photon echoes may be used to remove inhomogeneous broadening from an absorption spectrum and can therefore be very useful in analyzing complex samples.

In the above example of the pump–probe technique, both the pump and probe were laser pulses. However, lasers can also be used to make probes at widely varying wavelengths. In any event, the probe pulse is sent through another optical delay line and focused into the sample. One may temporarily replace the sample by a nonlinear crystal to determine at which setting of the optical delay lines the pulses overlap in the sample. Figure 18, the white-light probe is spectrally resolved by a spectrometer after the sample in order to measure the transient transmission spectrum of the sample. The signal measured as a function of the pump–probe delay time reflects the creation and destruction of chemical species in the sample. However, on short timescales (\(<1\) ps), there are numerous phenomena such as cross-phase modulation (see section 3.1) that may complicate the signal.\(^{45,60}\) A variation on the pump–probe technique is the photon echo.\(^{(56)}\) Photon echoes may be used to remove inhomogeneous broadening from an absorption spectrum and can therefore be very useful in analyzing complex samples.

and spatial resolution. There are many other examples of unconventional pump–probe techniques. The probe may consist of X-ray pulses, electron pulses or any other kind of pulsed particle beam. The only critical requirement is that the pulses in the pump beam are synchronized to those in the probe beam.

5 APPLICATIONS

As ultrafast lasers are becoming smaller and easier to use, they will find increasingly down-to-earth applications. For example, IR generation using ultrafast lasers may become so simple and cheap that its advantages can be used: spatially coherent beams (resulting in better focusing and directionality), coherent detection (allowing one to measure refractive indices directly without resorting to the Kramers–Kronig relations), broadband (allowing single-shot detection of an entire spectrum) and more power at “odd” wavelengths (especially in the far-IR region). One of the main advantages of ultrafast lasers is, of course, that they allow time-resolved experiments with which one can observe transient species. Another advantage is that short pulses with modest energy can have huge peak power. This makes femtosecond pulses very suitable for laser ablation of materials, multiphoton absorption (for imaging of biological materials), fragmentation (e.g. of DNA into fragments that may be analyzed using MS), etc. The high peak power also permits the efficient conversion to other wavelengths using nonlinear crystals. A slightly unexpected recent observation is that when femtosecond lasers are used for machining the resulting cuts are much cleaner because the laser pulses turn the material into a plasma rather than melting it. The number of applications of ultrafast lasers is already large and will only grow. It would be impossible to describe all these applications in the limited space available here. Therefore, a few key applications will be described.

5.1 The Study of Fast Chemical Reactions

In principle, there is no difference in the information that can be obtained from a frequency-resolved or a time-resolved experiment. In a frequency-resolved spectrum, a vibronic transition may show up as a series of sharp absorption lines. In the equivalent time-resolved experiment, one will observe quantum beats whose periods correspond to the inverse of the spacings between the absorption lines. In practice, however, there may be differences. For example, even in the gas phase, the spacing between the absorption lines may be so small that it is hard to resolve them. More importantly, in the solution phase, the molecule under study will couple to the degrees of freedom of the surrounding bath. Strictly, the Schrödinger equation for the liquid could be solved, which would show that the dynamics in the liquid in fact correspond to about one-trillion-trillion \((10^{24})\) well-defined quantum states. Most of these bath states will be coupled to the vibronic states in the molecule, resulting in the broadening of the transition. In such a case, a spectrally resolved experiment will provide little information about the dynamics of the molecule or the dynamics of a chemical reaction that one would like to study. Even hole-burning spectroscopy will not provide much more information in most cases. Only time-resolved pump–probe techniques can elucidate the molecular dynamics.

In the 1980s and 1990s, a series of experiments were performed by a variety of groups which came to be known as “femtochemistry” or “femtobiology”. These experiments exploited the property that if a molecule is excited with a laser pulse shorter than the oscillation period of relevant vibrations in the molecule, a coherent vibrational wavepacket is created in the excited state (see Figure 20a and b). Vibrations with a period shorter than the pulse width are simply not coherently excited and do not give rise to quantum beats.

The “hydrogen atom” of femtochemistry is the diatomic molecule NaI that was extensively studied in the gas phase.\(^{13}\) When NaI is excited by a femtosecond UV pulse (see Figure 21a and b), a wavepacket is created on the repulsive excited state, which (at large interatomic distances) corresponds to the ion pair Na\(^+\) and I\(^-\). However, this repulsive potential forms an avoided crossing with the ground-state potential, which (at large interatomic distances) corresponds to the radical pair Na + I. If the system is probed in the excited-state potential well, it is seen that the wavepacket coherently oscillates...
in the bound state. However, if the sodium radical is probed by inducing fluorescence with the probe pulse, it is seen that the population of the radical increases in a stepwise fashion. Therefore, such an experiment shows that the chemical reaction (a dissociation in this case) is a quantum-mechanical process in which a fraction of the bound wavepacket tunnels to the state of dissociated radicals each time the wavepacket travels through the crossing region. Interestingly, it is possible to use quantum mechanical interference of wavepackets to steer a reaction in a desired direction and away from undesired directions. This is referred to as coherent control and has been applied on small molecules with varied success.

A study, such as that on NaI described above, becomes interesting if one can compare the behavior in the gas phase with that in the condensed phase. Various molecules that had been studied in the gas phase have now been studied in solution where again one could observe quantum beats due to vibrational wavepackets. Examples are HgI$_2$ and I$_2$. Vibrational quantum beats have now been observed in a large variety of molecules in the condensed phase, including proteins.

In these large, complicated systems, quantum beats provide a unique opportunity to determine the potentials relevant for chemical and biological reactions. Not least, the femtochemistry technique may be used to detect
short-lived intermediates that would be invisible when ordinary spectrally resolved techniques were used. A recent experiment has shown that femtochemistry can be combined with MS: pump and probe laser beams were crossed with a molecular beam and radical fragments were detected with MS as a function of pump–probe delay. The technique was used to study Diels–Alder reactions and the concept of concertedness and may well find more general use in analytical chemistry. Now that high-repetition rate, high-power lasers are available, ultrafast lasers may be used to make a variety of elusive molecules that normally occur only in the atmosphere or in space.

5.2 Imaging

Nonlinear ultrafast optics can be of immense value for (biological) imaging studies. Femtosecond lasers can be used to perform multiphoton absorption confocal-imaging studies. Using this technique, one can image the spatial distribution of one specific molecule inside a living cell. Tunable femtosecond NIR pulses are ideal for this purpose as scattering and damage to the cell are reduced compared with UV radiation. A new alternative involving THG at the focus of a microscope has been used recently in imaging applications. At an interface, giving rise to a slight change in refractive index or third-order nonlinear susceptibility, THG becomes phase matched. The UV light generated can be detected using a photomultiplier tube or CCD camera. The conversion efficiency is low (10⁻⁸), but at the tight focus of a high numerical-aperture objective lens, a fluence of 100–300 GW cm⁻² (a few nanojoules per pulse) is enough to generate a detectable third-harmonic signal without damage to the sample. The technique benefits from being background free. NIR light at 1.2 µm has been employed, giving a third-harmonic signal at 400 nm away from potentially harmful UV wavelengths, which would damage delicate (possibly living) specimens. The chirp induced by the lens is also much smaller in the NIR region. In distinct contrast to multiphoton absorption of samples tagged with fluorescent probes, no reduction in signal is observed over time since the sample is not repeatedly bleached. Scanning mirrors are used to provide traveling Lissajou patterns giving a nearly uniform sample illumination and the image is recorded on a CCD camera. An example image is shown in Figure 22(a). Here, a rhizoid (a tubular single cell) tip from chara plants (green algae) is shown. The bright spots are stratoliths, vesicles containing BaSO₄ crystals, which flow within the cell and are necessary for the gravitational response of the alga. The CCD camera detects the motion of these stratoliths over time. This example shows that the technique is applicable to the same systems as more conventional phase-contrast microscopy and will surely be developed further as techniques for optimizing the duration of the pulse at the objective are developed.

The frequency range between ca. 100 GHz and a few terahertz has not been studied very well, as not many light sources are available. FTIR spectrometers typically peter out at frequencies below about 50 cm⁻¹ (1.5 THz), even when equipped with bolometric detectors and far-IR optics. Microwave devices may go to frequencies as high as 1 THz but usually have poor tunability. However, this frequency range is of great interest as many low-frequency vibrational and rotational modes absorb here. The pseudo-band gaps of superconductors and inter-band gaps of semiconductor heterostructures are also in this range. An exiting new application of terahertz pulses is t-ray imaging. T-ray imaging was first performed at Bell Laboratories: a beam of terahertz pulses was focused to a tight spot and a sample was scanned through
the beam. Owing to the long wavelengths at ca. 1 THz, spatial resolution was limited to about 1 mm. However, because the transit time of subpicosecond terahertz pulses can be measured with an accuracy of a few femtoseconds (see Figure 22b), it is possible to make tomographic images. Thus, by measuring the internal reflections in a sample, for example, the various surfaces in a floppy disk, it is possible to detect hidden features with a depth resolution much higher than the wavelength. Very recently, several attempts have been made to improve the lateral resolution by applying near-field techniques such as using small apertures in front of the sample or terahertz pulse generation in subwavelength regions.

It was shown recently that electrooptic sampling can be performed in parallel using a large-area electrooptic crystal and an unfocused probe beam, thus allowing the acquisition of t-ray images in real time.

Using a technique analogous to ultrasound, optical-coherence tomography utilizing femtosecond lasers has permitted micrometer resolution in real-time imaging applications, particularly in biomedicine. Cross-sectional images are made in a similar manner to the terahertz-imaging application by measuring the “echo” time of backscattered light using interferometric methods. Since the axial resolution is limited by the coherence length of the light, short-pulse Ti:sapphire and particularly NIR Cr:forsterite lasers are seen as attractive sources. An image is measured by building up the backscattered pattern at several transverse positions and these high average-power lasers are ideal for imaging at a few frames per second.

5.3 Structure Determination: Electron Beams and X-rays

Time-resolved pump–probe spectroscopy has been used for a long time to study chemical reactions. Often such spectroscopy relies on excitation and probing at visible wavelengths and transient visible spectra have to be carefully analyzed and interpreted to find out what the reaction products are. More recently, several groups have started to use femtosecond IR pulses in the hope that transient IR spectra will give more direct information about which chemical bonds are broken or formed. However, neither visible nor IR spectroscopy provides direct information about the spatial atomic structure of a given reaction intermediate.

X-ray diffraction has been used for close on a century to determine the atomic structure of crystals. Especially in the life sciences this has resulted in a much better understanding of the structure of proteins and other biomolecules and hence to a better understanding of the fundamentals of biochemistry. Because of the great absorption of electrons by materials, time-resolved electron-diffraction experiments have so far only been performed in the gas phase and on surfaces. However, as steady-state electron diffraction has also been used to determine the structure of proteins in the solid state, femtosecond time-resolved electron diffraction in the solid state may also become a possibility. Electrons at present provide the most structural information for a given amount of radiation damage. The atomic cross-section of carbon for (elastic or inelastic) scattering of electrons is more than six orders of magnitude larger than that of X-rays. Furthermore, radiation damage by 80–500-keV (λ = 0.043–0.017 Å) electrons is 400–1000 times less than that of λ = 1.5 Å X-rays. Clearly, it would be a great advantage if one could apply the technique of diffraction on a femtosecond timescale. Modern synchrotron facilities such as the European Synchrotron Radiation Facility (ESRF) in Grenoble, France, and the Advanced Light Source (ALS) in Berkeley, CA, USA, now make it possible to study structural dynamics using time-resolved X-ray crystallography on a nanosecond timescale.

However, many chemical and biological reactions take place on a picosecond or even femtosecond timescale. Many research groups around the world are now working towards the goal of femtosecond timescale diffraction. The technology of generating femtosecond X-ray or electron pulses is described in sections 3.2 and 3.6.

A series of (sub)picosecond time-resolved electron-diffraction experiments was recently performed on gas phase samples in a molecular beam (Figure 23a and b). In these experiments, electron pulses were generated by exciting a back-illuminated photocathode with 400-fs 307-nm laser pulses at a 30-Hz repetition rate. The electron pulses (~6000 electrons) were then accelerated to 18.8 keV and focused with the 307-nm pump beam into a gas jet containing the sample. Two-dimensional electron diffraction patterns were recorded as a function of pump–probe delay using a CCD camera fiber-coupled to an image intensifier. The time resolution (determined by space–charge effects) was about 7 ps. In these experiments, dissociation reactions in, for example, CF2I2 and Fe(CO)5 were studied. The method allowed the observation of rare reaction intermediates and, most importantly, the determination of their spatial structure. Picosecond time-resolved electron diffraction experiments have also been performed on surfaces. For example, the effect of melting a Pb (110) surface has been studied.

Generating femtosecond hard X-ray pulses is much more difficult than generating electron pulses, which may explain the small number of unique experiments. All ultrafast X-ray diffraction experiments to date have studied the lattice expansion of semiconductors, metals...
Figure 23 (a) Schematic diagram of a time-resolved electron-diffraction experiment. A strong femtosecond laser pulse irradiates a metal target and produces femtosecond electron pulses. The electrons are accelerated by an electron gun and focused into a sample. Diffracted electrons are detected by an imaging multichannel array plate (MCP) and CCD detector. If the sample is pumped by another beam of femtosecond pulses, one can detect the change in the diffraction pattern induced by the pump. (b) Femtosecond electron-diffraction pattern. or organic films under intense laser irradiation. In such an experiment, one typically selects one diffraction peak and measures the amount of diffracted X-rays as a function of the pump–probe delay or the shift or broadening of the diffraction peak. The changes in the diffraction peak reflect, for example, the expansion of the lattice and sound waves bouncing through the crystal.\(^{112}\) It may be a while before the technique is mature enough to study the time dependence of complete diffraction patterns.
